Finally, biological mechanisms (and hormonal systems in particular) are central to the development and expression of human sexuality. Sexual behavior in humans, compared to that of most other primates, appears to be less tightly regulated by hormonal mechanisms. Indeed, human sexuality is characterized by its remarkable flexibility and diversity, much of which cannot be parsimoniously explained by biological forces. Nevertheless, there exists some hormonal influence on women's sexual behavior and preferences, which is modulated by partner characteristics, cultural norms, and environmental circumstances.

Human Sperm Competition

Robin Baker
School of Biological Sciences, University of
Manchester, Manchester, UK
Córdoba, Málaga, Spain

Definition

Human Sperm Competition The competition to fertilize a woman's egg between sperm from two or more different men.

Robin Baker has retired.

Introduction

Sperm competition was first studied in insects (Parker 1970), but was soon suspected to occur in other animals, including humans (Smith 1984). A series of publications (see **Robin Baker and Mark Bellis: Pioneers of Research on Human Sperm Competition**) claimed to have found evidence that confirmed this suspicion. These claims triggered a wave of opposition (see **Opposition to human sperm competition**).

Currently, authors are divided into three main groups. The first (e.g., Baker and Bellis 1995; Gallup et al. 2006) considers that sperm competition occurred sufficiently often in the human past to have been a major selective pressure on sexuality. The second (e.g., Dixson 2009; Larmuseau et al. 2016) proposes that human sperm competition happened rarely and has played either a minor or zero role in human evolution. The third (Marczyk and Shackelford 2010) maintains that the actual frequency does not matter. As long as sperm competition occurs with some predictability and carries large fitness costs, even a relatively low frequency can act as a powerful selective pressure.

For the moment this debate continues unresolved. Alongside this discussion, however, aspects of human behavior, psychology, physiology, and anatomy are being demonstrated that seem to make sense only as adaptations to sperm competition (Shackelford et al. 2016). A brief summary follows, divided into three sections. The first considers when, where, and how sperm might compete, and the next two consider the potential evolutionary impact of such competition on first male and then female sexuality.

Competing Sperm: When, Where, and How

The following descriptions are based on the review and extensive references in Baker and Bellis (1995).

Insemination

A man stores sperm in two long narrow tubes in his lower abdomen. Each tube (vas deferens)

extends from a testis to the single prostate gland. Inside this gland, the two tubes join the urethra (the duct that runs the length of the penis). While in the vas deferens sperm are highly concentrated in just a small amount of fluid from the testis. The maximum number of sperm stored in the two tubes at any one time is ~1000 million with older sperm nearer the penis and younger sperm nearer the testes.

A woman's unstretched vagina is more a slit than a tube. Protruding into the upper vagina is the cervix (the lower part of the uterus). The cervical opening ranges in shape from a circular dimple to a transverse slit. Inside the cervix the walls are lightly adpressed on a column of mucus that moves forever downward in glacier-like fashion eventually to drip into the upper vagina.

When copulation begins, the penis distends the vagina, everywhere touching the internal walls. Just before ejaculation a portion of each of the two "columns" of sperm is shunted from the vas deferens into the urethra. Ejaculation then follows. The upper part of the vagina dilates like a balloon, in effect creating a bowl to receive the semen.

While contractile waves force the sperm from the urethra, secretions from first the prostate then the seminal vesicles add volume. On average, ~300 million sperm in ~3 ml of semen are ejaculated in a series of 3–9 spurts, often with a copulatory thrust between each spurt. The result is an inseminate that for two reasons is neither homogenous nor all in one place. First, the seminal fluids differ chemically between spurts. The first part is dominated by prostate gland secretions and the later parts by fluids from the seminal vesicles. The very last spurt is strongly spermicidal. Secondly, the spurts are inseminated with different force by a penis that may change in length and turgor from first spurt to last. The end product is a "seminal pool" next to the cervical opening, plus semen from later spurts and dribbles lower down the vagina.

Sperm Competition It is not known what happens on the, presumed infrequent, occasions that a woman is inseminated by two males

simultaneously nor how the two ejaculates and contained sperm might interact if she does.

In Vagina

Immediately after, or even during, insemination, the cervix dips into the seminal pool, creating a cervical mucus-semen interface. Virtually simultaneously, most of the ejaculate, excluding the part nearest the cervical opening, coagulates to form a soft, gel-like structure which does not become liquid again for 15–20 minutes. Coagulation retains the seminal pool in position while sperm leave to cross the cervical mucus-semen interface.

After the seminal pool decoagulates, the upper vagina contains a mixture of the now-liquid-again seminal fluid, various female secretions, and stranded sperm. If the cervix dips again into this mixture, such as during female orgasm, more sperm can still escape into the cervix. If not, no more sperm can leave the pool. Eventually, the female ejects the whole mixture from the vagina as the "flowback."

The flowback exits the vagina as a discrete series of 3–7 white globules and measures ~3 ml; in effect the female rids her vaginal tract of virtually all of the seminal fluid plus any sperm still contained. This event occurs between 15 and 120 min after the male ejaculated (0–105 min after the seminal pool decoagulates). If expelled during urination, the flowback is sometimes ejected with surprising force.

All flowbacks contain sperm, on average ~35% of the number inseminated (range: 5% to ~100%).

Sperm Competition Only when a woman mates with a second male before ejecting the flowback from the first male do two ejaculates interact inside a vagina. In the UK, ~1% of women with >500 lifetime copulations claimed at some time to have been inseminated by two different males within <30 min (Baker and Bellis 1995). In the USA, ~8% of college undergraduate women claim to have engaged in group sex (1 woman, 2 or more men) at least once (Gallup et al. 2006). On most such occasions, the second male will remove the first male's ejaculate with his penis (see section on '[Penis shape and copulatory behavior](#)' below) before himself ejaculating. If he does not, however, the two ejaculates interact in the vagina.

There are two phases and elements to this interaction. First, for ~15–20 minutes after the first male ejaculated, his coagulated seminal mass can function as a short-term plug, a physical barrier that keeps sperm from the second ejaculate away from the cervix. Secondly, after decoagulation, the spermicidal back part of the ejaculate from the first male could decrease the motility and survival of sperm in the second male's ejaculate. Counteracting this, however, the prostatic first half of the second male's ejaculate provides some protection to its contained sperm.

In Cervix

Cervical mucus has a complex structure with fibrils arranged to form channels. Sperm migrate through the mucus by way of these channels. There are two channel arrangements within a cervix: vertical, aligned more or less parallel to the cervical walls, and diagonal, running from the lower (vaginal) end of the mucus column to crypts in the cervical wall. Compared with a sperm, which is ~3 μm wide, the vertical channels are spacious (30–35 μm), whereas those through the diagonal mucus are relatively narrow (2–6 μm). Proportions of the two types vary over time with vertical channels dominating during the fertile phase of the menstrual cycle.

The dipping of the cervix into the seminal pool allows sperm to escape from the vagina. The mucus-semen interface consists of a series of finger-like projections of semen extending a short way into the mucus channels. Once across the interface, sperm then swim either through the vertical mucus, perhaps directly to the uterus, or along the diagonal channels into the cervical crypts.

Around 65% of sperm from an inseminate successfully enter the cervical mucus, but the vast majority then go no further. Within minutes of first sperm entry, the female floods the mucus with white blood cells (leucocytes). These attack the invaders, killing and removing them by phagocytosis, targeting healthy sperm just as aggressively as the dead, and dying. At their peak, a few hours after insemination, leucocytes may outnumber sperm by up to 3:1. Within

24 hours of insemination, however, leucocyte numbers have returned to base level.

Only ~1% of sperm (~3 million) from the inseminate successfully evade the leucocytes. Some that do so pass straight through into the uterus, but the vast majority instead find safe haven in one of the 10,000 or so crypts that dot the cervical walls. While in these crypts, safe from phagocytosis, the sperm become immotile until expelled. Expulsion occurs suddenly but is staggered over days with a peak 24 hours after insemination.

Sperm Competition Most (~99%) sperm that enter the cervical mucus never leave alive, reaching neither the uterus nor the crypts. Instead, they are either intercepted by leucocytes or simply lodge in the mucus. Even these sperm, however, can play a part in sperm competition. By blocking channels through the cervical mucus and attracting leucocytes, they can greatly hinder the passage of sperm from any second male that inseminates the female over the next day or so.

Competition can also occur in and around the cervical crypts. As sperm from a second male attempt to enter and settle in these crypts, then later jostle after expulsion, the presence of sperm from a previous male can interfere with both maneuvers.

In Uterus

Except when pregnant, a woman's uterus (womb) is roughly pear sized as well as pear shaped with the walls pressed closely together. Vanguard sperm that swam straight through the vertical channels of the cervical mucus arrive within 5 minutes of insemination. These are then helped to the womb's top, the widest part of the pear. In effect, they surfboard, carried on the crests of muscular ripples passing up the walls. At the top of the womb on each side, where horns would be if the "pear" was a bull's face, is an opening (the uterotubal) leading into a narrow tube, the oviduct. Once through the opening, the sperm swim a short distance along the oviduct until reaching a rest area (the isthmus). Here most cease swimming, settle down, and wait.

The wave of sperm that passes through the uterus just minutes after insemination is neither

the largest nor the last. Numbers in the uterus peak ~24 hours after insemination as further sperm arrive following expulsion from the cervical crypts.

Sperm Competition The uterus seems merely a zone that sperm must traverse to reach the oviduct. As it is possible to arrive in the oviduct too soon as well as too late, sperm from two or more men are not really “racing” during the traverse. Only if early sperm can hinder later sperm in some way (e.g., by blocking the uterotubal junction or occupying better positions in the oviduct), does there seem scope for competition during this leg of the journey.

In Oviduct

Fertilization occurs in the ampulla, the region of the oviduct furthest from the uterus. Beyond the ampulla is an opening into the female’s body cavity near one of the two ovaries. Roughly every 2 months, a particular oviduct receives an egg, which then remains fertile for only ~24 hours.

Only ~25,000 sperm from an inseminate of ~300 million ever pass through an oviduct. At any one time only ~3500 are present and of these only ~300 are in the ampulla. Most often, after several hours residing in the isthmus, sperm set off individually to swim to and through the ampulla then on into the body cavity where they die. However, on those rare occasions that an egg is released by the nearby ovary, a chemical “signal” arrives, and many sperm from the isthmus swim to the ampulla simultaneously. Whether an egg arrives or not, 4–5 days after a single insemination, there are no sperm left in the oviduct.

Sperm Competition A sperm’s timing of arrival at the ampulla may be more important than speed. However, when an “egg-approaching” signal is given, the swim from isthmus to ampulla might become a race.

Fertilization

A single insemination is most likely to lead to fertilization if it occurs 48 hours before ovulation, which is roughly the time taken for the sperm

population to peak in the oviduct. However, not all sperm even in the oviduct are able to fertilize an egg: only 1 in 7 have such ability (compared with an even lower 1 in 300 in the original inseminate). This means that of the ~25,000 sperm that pass through the oviduct, only about ~4000 are capable of fertilization, and of the 300 found at any one time in the ampulla, only ~40.

Sperm Competition It is generally assumed that when sperm from two or more males compete inside a female, the male who has most sperm in the ampulla as the egg arrives has the greatest chance of fertilization. Whether the critical factor is “most sperm” or “most sperm capable of fertilizing an egg” is not yet clear. Much depends on the function, if any, of the 86% (6/7) in the oviduct not capable of fertilization. Two explanations have been offered: (1) that these sperm are faulty, hence irrelevant, and (2) that they hinder, divert, or even kill fertile sperm from rival males.

Selection on Men

Human males, whether paired to women monogynously (1:1, male/female) or polygynously (1:>1, male/female), invest significant time, energy, and “wealth” into raising their partners’ children. Evolutionarily, a male gains most if these children are his own genetic offspring (Trivers 1972). Sperm competition, due to a partner’s infidelity, threatens a male’s reproductive success because it raises the possibility of cuckoldry, leading a male unknowingly to expend resources on raising another man’s child. Selection, therefore, favors a man who either prevents sperm competition or, if he fails, ‘wins’ the competition that ensues.

Pham and Shackelford (2014) contrast the “risk” and “intensity” of sperm competition: risk refers to the likelihood that the male’s sperm will face competition, while intensity refers to the number of males that contribute sperm to that competition. Shackelford (2003) proposes that human males encounter three separate adaptive problems from sperm competition: anticipation, prevention, and correction. The first two are

generated by risk and lead to adaptations that motivate mate choice and guarding. The last is generated by intensity and leads to adaptations such as copulatory behavior, genital morphology, ejaculate qualities, and the number and behavior of sperm. Some behaviors, such as routine sex, are adaptations to all three problems.

Anticipation: Mate Choice

Males who choose more-faithful long-term partners are less likely to encounter sperm competition, and evolution should favor men who can reliably identify such women.

Men show agreement on which women are likely to be unfaithful, their judgment seemingly based on female attractiveness. There is also some evidence that this judgment has foundation. Women with features shown to be attractive to men (e.g., low waist-to-hip ratio, bilateral symmetry, and feminine voices) have been reported to accumulate more sexual partners, including committing more acts of infidelity (Baker 1997; Hughes et al. 2004; Shackelford and Buss 1997; but see Rhodes et al. 2005).

Prevention: Mate Guarding

Once committed to a relationship, a man shows some ability to judge his partner's faithfulness (Andrews et al. 2008), in part by analyzing her behavior (Shackelford and Buss 1997). He can also assess to a degree whether any child she bears is likely to be his genetic offspring (Anderson 2006).

Buss (1988) identified 19 male tactics that reduce sperm competition including surveillance, threatening rival men, and direct guarding (i.e., spending as much time with the partner as possible). Such guarding succeeds: in the UK the more time a man spends with his partner between copulations, the less likely she is to be unfaithful (Baker and Bellis 1995). A man can also recruit other family members to keep surveillance on his partner in his absence (Strassmann et al. 2012).

Some men attempt to enforce fidelity through violence and in places have their actions supported by law. The earliest known example, from 4300 years ago, is found in the Mesopotamian Code of Urukagina (French 2008) which

advocated stoning unfaithful women to death. A number of modern societies still allow a death sentence for females accused of infidelity.

Correction

Despite men's attempts to prevent partner infidelity, they do from time to time fail. Estimates of the proportion of children sired by a man other than their putative father range from ~10% (Baker and Bellis 1995; Anderson 2006) to ~1% (Larmuseau et al. 2016) (see **Opposition to human sperm competition**). Perhaps in consequence, men also show adaptations that seem to increase their chance of "winning" any sperm competition that results.

Routine Sex

Men seem motivated to maintain a population of sperm inside their partners, and the greater the risk of sperm competition, the larger the population maintained (Baker and Bellis 1995). This adaptation *anticipates* partner infidelity, *guards* against another male's sperm having uncontested access to the partner's egg, and provides some chance of *correcting* the female's infidelity by still being the male to fertilize her egg.

The strategy a man is suggested to use (Baker and Bellis 1995) is to maintain reservoirs of sperm in his partner's cervical crypts, thereby ensuring a continuous passage of fresh sperm through her oviducts for up to ~5 days after each insemination. Intercourse at least every 5 days is sufficient, combined with varying the number of sperm inseminated according to time since last copulation.

Over a period of 4 weeks, the total number of sperm inseminated into a partner averages about 3000 million and varies little whether the couple have sex 20, 10, or 5 times in that period (Baker and Bellis 1995). However, if the man spends less time physically "guarding" his partner between copulations and the risk of sperm competition increases, the total number of sperm he inseminates also increases (Baker 1997).

Masturbation

A recent (<72 hours) masturbation reduces the number of sperm inseminated at the next copulation but not the number that enter the cervix

(Baker 1997). Such masturbatory “shedding” may increase inseminate competitiveness by removing older sperm. Thus, at the next copulation, the male inseminates younger sperm which could survive longer inside the female. Potentially, masturbation is an adaptation to sperm competition.

Response to Sight of a Copulating Pair

Males of many species respond to perception of a copulating pair by attempting either to oust and take over from the other male or, failing that, to mate with the female as quickly thereafter as possible (review: Baker and Bellis 1995). To achieve this, perception of a copulating couple needs to generate a rapid arousal for copulation and the sperm competition that inevitably follows. In male humans the appeal of hard-core pornography rests on such a response. Surveys have shown that men prefer images of a woman with multiple men, suggesting sperm competition, compared to those of a man with multiple women (McKibbin et al. 2013).

Urgent and/or Forced “In-Pair” Copulation

Just as with directly observed infidelity, a man who strongly suspects his partner of recent infidelity increases his chances of avoiding being cuckolded by inseminating her himself as soon as he can. This is especially the case if he suspects the infidelity to be very recent (<2 hours). Until the flowback from the previous male is ejected, that male’s sperm can still be entering the cervix (Baker and Bellis 1995).

Men who spend a greater percentage of time absent from a partner report greater sexual interest in that partner, greater distress in response to sexual rejection, and a greater sexual persistence if rejected (Shackelford et al. 2007). This increased drive to inseminate a partner suspected of infidelity can lead to force being used (Wilson and Daly 1992): most forced within-pair copulations follow accusations of female infidelity.

Penis Shape and Copulatory Behavior

Until ejected in the flowback, one male’s semen can hinder any second male’s sperm trying to enter the cervix, but this earlier semen can be removed.

The erect human penis is piston shaped with a smooth terminal protuberance (= coronal glans). This shape, the fit of the penis in the vagina, and the pumping/thrusting action during copulation together mean that as a penis pushes forward then pulls back, semen already present is sucked down the vagina. On the next forward thrust, the glans pushes through this material; then on the next backward pull, the back edge of the glans scrapes the material further down the vagina in a “push-pull-suck-push-pull-scrape” process (Baker and Bellis 1995). This process has been verified by Gallup et al. (2003) using artificial penes, vaginæ, and semen. Gallup et al. also reported that after a perceived female infidelity or period of female absence, males thrust deeper, faster, and more vigorously.

Testes Size

Males of primates with high levels of sperm competition have proportionately larger testes (relative to body size) than males of species with low levels (Harcourt et al. 1995). Larger testes produce more sperm at a faster rate. Evolutionarily, in lineages with greater sperm competition, the organs increase in size until the gain from greater competitive success is opposed by some other factor (e.g., cost of maintaining larger testes, or greater risk of damage). Relative testes size for humans is ~4 times greater than for gorillas (with low sperm competition) but ~5 times smaller than for Chimpanzees (with high). This suggests an evolutionary past for humans with intermediate levels of sperm competition.

Testes size varies greatly within populations. Baker and Bellis (1995) hypothesized that men with larger testes are specialized for sperm competition and men with smaller testes for mate guarding. Between the two extremes, men follow a mixed strategy. In support of this hypothesis, men with larger testes: (1) spend less time with their established partner (Baker and Bellis 1995), (2) show less interest in their partner’s children (Mascaro et al. 2013), (3) copulate and ejaculate more frequently (Baker and Bellis 1995), (4) inseminate more sperm at each copulation (Baker 1997), (5) ejaculate more sperm during masturbation (Baker 1997; Simmons

et al. 2004), and (6) are more likely to become involved in sperm competition (Baker 1997; Baker and Bellis 1995; but see Simmons et al. 2004).

Sperm Morphology

Human ejaculates contain a proportion (up to 40%) of strangely shaped sperm. Head shape, for example, can be small, large, pear shaped, cigar shaped, or simply oddly shaped. Tails vary too: short, bent, coiled, or double. Traditionally, such sperm have been blamed on mistakes during sperm formation (Cohen 1977). However, Baker and Bellis (1988) suggested that they were adaptations to sperm competition, some even present specifically to die, a “kamikaze” role (see: **Robin Baker and Mark Bellis: Pioneers of Research on Human Sperm Competition.**)

Selection on Women

Most discussion surrounding sperm competition focuses on males, but females also gain benefits (Smith 1984). If sperm competitiveness is heritable, females fertilized by the most competitive sperm will gain through the greater reproductive success of their sons. To obtain this advantage, a female needs to promote sperm competition via *double mating* (matings that lead to the presence of sperm from two or more males inside her reproductive tract) at around the time of peak fertility.

Weak Signals of Fertility

To double-mate a female must, at key moments, evade mate guarding by her established partner. Several adaptations have evolved to make such evasion easier (review: Welling and Puts 2015).

Female humans are sexually receptive both throughout the menstrual cycle and during pregnancy. This background receptivity makes it more difficult for male partners to identify the critical days to guard the female intensively. Nevertheless, females do not, and maybe cannot, hide their fertile phase completely.

“Oestrous” is the phase of the female cycle leading up to and just following ovulation. During this phase a suite of attributes appear, all of which

are less pronounced at other times. In humans, not only do females travel further and show more interest in mating with multiple males at this time (Baker and Bellis 1995), but also they advertise their phase of cycle through subtle changes in appearance, behavior, attitude, sound, and smell (review: Welling and Puts 2015).

How effectively men can detect and act upon the oestrous signals given by women is still debated, but clearly they cannot interpret the signs with total certainty (see Welling and Puts 2015). For example, men of the agricultural Dogon tribe of Mali forced their wives to advertise menses by temporarily residing in special “menstrual” huts. When menstruation finishes, the wives are then for a while kept under intense surveillance by their husband’s family network. Consequently, the number of Dogon children fathered by a man other than a woman’s husband was low (Strassmann et al. 2012). However, when a section of the population relaxed its use of the menstrual hut, the frequency of such “extra-pair” paternities increased fivefold, suggesting that direct detection of the fertile phase by males was weak at best.

Timing of Double Mating by Women

Nationwide data for women in the United Kingdom revealed that general female infidelity showed no pattern with respect to the menstrual cycle (Baker and Bellis 1995). However, double matings “unprotected” by contraception were most likely to occur during the fertile phase, suggesting that the women were most likely to promote sperm competition when the probability of conception was highest (see **Robin Baker and Mark Bellis: Pioneers of Research on Human Sperm Competition** for more details).

Cryptic Female Choice

Women use a range of information when choosing long- and short-term partners (Shackelford et al. 2016; Welling and Puts 2015) and make comparisons between the two when promoting competition between their sperm. Females also have a variety of adaptations that allow them to bias the chances of fertilization in favor of a particular male.

Although such “favoritism” is not shown by younger nulliparous women, it is shown by women in the main reproductive phase of their lives (Baker 1997). The latter are less likely to use contraception during sex with a male who is not their established partner. They also, by altering the occurrence and timing of their orgasms, seem to retain more sperm from this other male than from their partner.

For further details of this function of the female orgasm plus opposition to the findings, see **Robin Baker and Mark Bellis: Pioneers of Research on Human Sperm Competition**; for a general review of the female orgasm, see Puts et al. (2012).

Conclusion

Debate continues over whether sperm competition occurred often enough in the past to play a significant part in the shaping of human sexuality. Yet at the same time a body of work is amassing, covering many aspects of human behavior, psychology, physiology, and anatomy, that seems to make sense only in terms of adaptation to sperm competition.

Human sperm have a long and complex journey ahead of them when they are first inseminated into a vagina, and most falter within minutes or hours. An average of ~35% never escape the vagina and <1% ever get further than the neck of the womb (the cervix). Each leg of the journey raises its own unique circumstances and, when sperm from more than one male are present, raises different types of opportunity for those sperm to meet, interact, and compete.

The threat of sperm competition appears to have imposed a range of selective pressures on men. Advantages can be gained from preventing such competition, but when preventive measures fail, the only adaptive avenue is to try to win the sperm competition that then ensues. Sexual psychology, mate choice, mate guarding, masturbation, copulatory behavior, ejaculate size, penis shape, testes size, and sperm morphology have all been argued to have been shaped by sperm competition.

The evolutionary impact of sperm competition is not limited to males. Females would also appear

to gain by promoting such bouts. Various behaviors and attributes may all have evolved to aid such promotion; So, too, may responses such as sperm ejection and orgasm (female) that could influence the outcome of any sperm competition the female generates.

If the opposition to the role of sperm competition is justified, then all of these apparent adaptations will need to be explained in other ways. However, if sperm competition has indeed been the force that many scientists claim, it has been a highly significant factor in the shaping of human sexuality.

Definition

The process of sharing stories with other people generally for the purpose of entertainment, education, and promotion of cultural awareness and societal values.

Introduction

“Once upon a time” or the less common variant “once there was not” (Sherman 2008, p. 29) probably initiated everyone’s favorite story as a kid. There are many definitions of the words story, narrative, and storytelling, and at times they are even used interchangeably; nevertheless, a story is defined as the conceptualization of a sequence of events, a narrative is the concrete means of communicating a story to other people, and storytelling is the process by which narratives are composed, where the conceptualization of the story is turned into a material product, i.e., a narrative through an available medium, e.g., language and other nonverbal mediums such as pictures and miming (Sibierska 2017). Even though there are different types of stories, they can all, more or less, be separated into four main genres: true stories, folklore, fiction and literature, and fairy tales (Sherman 2008, p. 19).

A Bird’s-Eye View into Storytelling

Sherman (2008, p. 17–18) reported that the oldest record of written storytelling goes back as far as the second millennium BCE; around 2560 BCE, Egyptian records show that the sons of Pharaoh Khufu (or Cheops) used stories to entertain their father. Additionally, he stated that stories most probably predate their written versions. For instance, during the fifth century BCE, the Greek fabulist Aesop and, during the eighth century BCE, Homer (the famous Greek poet who wrote the epics “Iliad” and “Odyssey”) almost certainly recited their tales long before they had a chance to be written down. According to the author, in the course of the Middle Ages, the names of proficient storytellers started to be

systematically recorded, while throughout the Renaissance era, storytellers begun to attract attention and gain popularity.

Dennehy (1999) indicated that the narration of a story is comprised by five steps that are interdependent to each other’s content:

1. “Establishing the setting” – describes the various details of the situation (e.g., names, time, place, etc.) that foster a sense of connection between the story and the audience and also enables the listeners to mentally visualize the story’s circumstances.
2. “Building the plot” – this step builds up the listeners’ excitement and interest to the unfolding events of the story while taking advantage of their emotions so that audience identifies with the plot.
3. “Resolving the crisis” – the “ah-ha” experience which involves the realization of the story’s main point(s).
4. “Describing the lessons learned” – the story’s messages are made clear ensuring that everyone understands since some listeners may not outright realize the main point conveyed in the story (depending on the audience the key lessons of the story may vary).
5. “Explaining how the characters change” – listeners once again are prompted to identify with the story and reflect on how they can adopt the new values and behaviors portrayed in the key lessons of the story (as cited in Yoder-Wise and Kowalski 2003).

Lipman (1999, p. 17–18) described that the storyteller, the audience, and the story constitute the three corners of the “storytelling triangle” and that these three elements are accompanied by relational forces in-between them. The first relationship is between the storyteller and the audience, the second is found between the storyteller and the story, and the third is the one that the storyteller cannot force control over and can only affect indirectly, which is the relationship between the story and the audience. Subsequently, the goal of the storyteller is to form a positive bond between the story and the audience, a relationship that can only be established indirectly by the storyteller’s skills and abilities to persist, create a novel plot,

prepare, and genuinely care for both the story and the audience.

Role in Evolution

Despite the fact that language is considered the most popular way to tell a story, it is by no means the only modality available, which is evident by nonverbal narratives that are expressed through the use of pictures, facial expressions, body movements, and hand gestures (Sibierska 2017). McBride (2014) proposed that storytelling originated from mimes, long before there was any possibility of telling stories through the use of language, which would use gestures to impart their experience of the hunt. In addition, the author advocated that since stories would bestow more knowledge than juveniles could potentially learn on their own, they would eventually lead to mature and socialized adults that assembled the first forms of human cultures, from there on language evolved as the means to make the use of storytelling easier and more efficient. The storytelling brain separates humans from animals as it allows for meaning to be derived from metaphors and narratives to be interpreted and applied into real-life events (Le Hunte and Golembiewski 2014).

Over time human evolution ensured that it would be no longer necessary to live a situation in order to gain insight into potential threats or opportunities and humans would possess the evolutionary advantage to recognize and compare patterns in different situations or narratives allowing them to experience the perspective of others (Le Hunte and Golembiewski 2014). Storytelling is a skill assumed to be favored by natural selection because (a) children would receive important lessons from stories of experience hunters in a playful manner that would make them more adept as future hunters, (b) individuals talented at storytelling would receive more attention from their species hence gain more status and respect in their society, irrespective of rank, that could even make them more likely to be chosen as a sexual partner, (c) by hearing more stories experience troops learned from their peers about dangers and others' failures or successes which they

could later avoid or repeat without wasting unnecessary lives, and (d) storytelling's ability to pass on knowledge without directing communication through a double interaction, i.e., a primary social/interpersonal interaction between two or more individuals that contains a secondary interaction which is the story (McBride 2014).

Throughout years of evolution, neurological mechanisms in the brain have developed that allow the human species to effectively process and reflect on stories (Le Hunte and Golembiewski 2014). The brain components, found in both brain hemispheres, that assist these neurological mechanisms include the hippocampus where its role in storing and recalling information enables listeners to process the details of the story, within the temporal lobes the amygdala's function in processing emotions grants contextual awareness enabling the listener to identify or separate himself from the story, and lastly the frontal cortex act as an inhibiting agent for these storytelling mechanisms so that individuals can choose the story they want to concentrate and focus on (Le Hunte and Golembiewski 2014).

Why Do We Even Bother?

The storytelling occasion is a two-way street: as for the audience it is an opportunity to play, bond with friends, and share an experience together with a group, but for the effective storyteller, it is a moment of unconditional acceptance by the crowd (Sherman 2008, p. 18). To an even larger extent, when a father tells his son a story, societal values are passed down from one generation to the next, and when other groups of individuals hear those stories, it can help promote intercultural awareness (Sherman 2008, p. 18).

Some of the many benefits for students from the educational properties of hearing stories include but are not limited to learning about different cultural backgrounds, increasing the self-worth of immigrant or minority children who listen to their cultural values, aiding children to hone their listening skills, and improving the use of imagination, and by listening to the experienced storyteller, they are indirectly trained to become better storytellers, writers, and readers

themselves (Sherman 2008, p. 29). This is concurrent with current research findings that illustrate that in children there is a positive relationship between receptive and expressive language abilities along with their storytelling abilities (Holmes et al. 2017).

According to Sherman (2008, p. 18–19), individuals who hear a tale are presented with the opportunity to acquire another perspective to an adversity, gain access to an effective role model that prevailed in a challenging situation, expand their imagination to new heights, and overall develop on a personal level, while stories filled with intense emotional content promote a climate of compassion and caring that cultivates the feeling of togetherness among a group of people. What is more, the author stated that children listeners improve on their vocabulary knowledge, understanding of a narrative's structure, verbal ability to retell the story, and sense of self-worth. However, caution is advised when interpreting meaning from tales as the mind is biased toward detecting positive patterns and inferring meaning in stories where none exists (Gottschall 2012, p. 103–105), for example, “pareidolia” is the psychological phenomenon where the mind associates a familiar pattern to a stimulus even though one does not actually exist (e.g., seeing a face from a stain).

Conclusion

As discussed, human storytelling offers many evolutionary and developmental benefits while simultaneously is a largely entertaining and readily available resource to draw upon. For instance, the “catch-phrase” can often conveniently remind us of a tale and the accompanied moral point so that we can reevaluate our course of action (Sherman 2008, p. 18). Without undermining traditional storytelling, the technological advancements that increase exponentially year after year suggest that storytelling's future lies inside the virtual world and toward the direction of MMORPGs (massively multiplayer online role-playing games) where individuals can immerse their selves in a story shared with millions of other people that come from different ethnic backgrounds (Gottschall 2012, p. 177–200).

Human Tool Making

Arthur C. Durband
Kansas State University, Manhattan, KS, USA

Synonyms

Flintknapping; Human tool manufacture

Definition

Human manufacture of objects designed to achieve particular results.

Introduction

A tool is an object that can be used to achieve a particular desired result. The use of tools and the tools themselves are referred to as technology. Tools may be relatively simple and unmodified objects, such as rocks or sticks, or may result from modification of raw materials, with chipped stone tools or metal objects as examples. It was long assumed that only humans were able to use tools, but subsequent observations of tool use in a number of species like chimpanzees, monkeys, otters, and several types of birds have changed that perception. Nonetheless, human tool manufacture and use is quite complex and has been an important contributor to human adaptation in a variety of contexts.

Human Tool Making

It is likely that the earliest use of tools by human ancestors incorporated organic materials that are unlikely to be preserved in the archaeological record and that these are similar to tools like sticks, leaves, and other objects used by chimpanzees today. After stone was adopted as a raw material, however, long-term preservation became much more probable. At present, archaeological evidence suggests that humans began manufacturing simple stone tools sometime prior to about 2.5 million years ago. These first tools were made through relatively simple flaking along the edge of a rock to create a crude chopping tool. Such tools are inconsistently manufactured and did not require much skill to make, but research has demonstrated that chimpanzees lack the coordination necessary to produce the flaked edges seen on these tools.

The most basic stone tools fall into a small number of categories: manuport, core, hammerstone, and flakes. Manuports (derived from the

Latin for “carry by hand”) are unmodified stones that have been moved to a particular site by human agency. These stones are typically far removed from their source and could not have been moved to the site without human intervention. A core is a piece of stone that has had flakes removed from it. A hammerstone is used to remove flakes from the core. Flakes are small pieces of stone removed from a core, which can either be simple waste (debitage) or could also be used as tools themselves. The raw materials used to make stone tools were quite variable in the earliest examples, while more recent technological complexes show greater care in choosing higher quality stone that will flake more predictably.

The broad divisions of the Paleolithic (Stone Age) fall into the Early/Lower Paleolithic, Middle Paleolithic, and Late/Upper Paleolithic. The Early Paleolithic includes the Oldowan and Acheulian stone tool complexes. The Oldowan is the earliest stone tool culture and is characterized by simple choppers made from fairly crudely flaked stone cores, while the Acheulian is characterized by large, teardrop shaped bifacial handaxes. Unlike the more irregularly shaped choppers of the Oldowan, the Acheulian is more consistent in design and more skill is required to manufacture them. The Middle Paleolithic, sometimes referred to as the Mousterian, is typified by a variety of smaller tools struck from a prepared core. Typically multiple tools could be removed from a prepared core, greatly improving the efficiency of raw materials. The Late Paleolithic is characterized by stone blades, which require high quality stone and significant skill to produce. Additional tool types, such as points, scrapers, and awls, are present in the Late Paleolithic and incorporate a variety of raw materials besides stone, such as bone and antler.

Conclusion

Technology provided an important set of flexible adaptations to a variety of environments, allowing humans to range across the surface of the Earth. The evolution of tools throughout our history,

continuing through our present day dependence on a variety of gadgets, serves to highlight our reliance on innovation as a strategy for dealing with a number of obstacles in daily life.

Definition

Human visual neuroscience is an interdisciplinary field of study which seeks to understand the processing of visual information by the eye and brain in humans and provides a well-studied model of how sensory systems enable organisms to interact with their environments.

Introduction

Objects in the environment reflect light rays onto the retina which are transduced by photoreceptors into electrochemical impulses, and this information is sent to the occipital lobe for initial computation before being sent to higher-order brain regions for more modular processing. Visual neurons detect where objects are located in space by signaling only when an object in the visual field is presented in a specific position, known as its receptive field. As an example, a neuron in the right primary visual cortex may only signal in response to a black vertical bar but will only do so if it is located in a specific position in the visual field. Similar to the somatotopic maps of the somatosensory system or tonotopic maps of the auditory system, the visual neurons contained within the lateral geniculate nucleus of the thalamus and primary visual cortex maintain an organized map that detects spatial location and transduces it into a physiological portrayal of the visual field. These topographic maps in the visual system are known as retinotopic maps. The left-hemisphere of the primary visual cortex contains a complete retinotopic map of the right visual field and the right-hemisphere contains a complete retinotopic map of the left visual field (Gazzaniga et al. 2019). The primary visual cortex, otherwise known as area V1, acts as the first level of cortical visual processing. Neurons in the primary visual cortex are activated in response to specific characteristics of the visual world which include orientation, movement, spatial frequency, retinal disparity, and color.

The Primary Visual Cortex

Definition: The primary visual cortical area, anatomically defined as Brodmann's Area 17 or the

striate cortex, receives the axons of third order afferent visual tract neurons projecting from the lateral geniculate nucleus, which in turn receives afferents from retinal ganglion cells. It is the first cortical location that visual information reaches during vision processing.

Structure: Retino-Geniculo-Cortical Tract

It is no secret that many processes in life can be understood through a careful examination of their structure. If you want to know how a car engine works, one approach would be to begin by examining the underlying parts and how they interact with one another. This approach is based on the idea that function and form influence each other. This notion is thought to hold true of the brain as well. Therefore, to begin to discuss the function of the human visual system, it becomes critical to have a fundamental understanding of the underlying anatomy.

To make better sense of the anatomy, an awareness of the terminology related to the visual system must be appreciated. The retina is the portion of the eyeball which contains cells from the central nervous system. It is found at the back of the eye and receives input from the external world in the form of light. It can be grossly separated into the peripheral retina and the macular retina. The peripheral retina, unsurprisingly, makes up our “peripheral” vision. The macula makes up the center of our visual field. A shallow depression in our macula, termed the fovea, makes up the part of the retina with the highest visual acuity. When we speak of our visual field, we often divide it into quadrants, such that we have an upper outer, upper inner, lower outer, and lower inner quadrant with each eye. Due to the location and structure of the eye, and concave structure of the retina, our retina receives information from the visual field that is upside down and backward of its location in the retina. For example, the inferior temporal portion of our retina receives light input from the upper inner portion of our visual field. Similarly, the superior nasal retina receives input from the lower outer portion of our visual field, and so on.

Visual information begins its neurological journey in the retina. Information in the form of photons interacts with first order neurons called

cones and rods, is then converted to chemical and electrical signals, and is transferred to second order neurons called bipolar cells. The information is then modulated by interneurons (amacrine and horizontal cells) and is passed along to ganglion cells. There are two major types of ganglion cells: alpha (or M cells or magnocellular cells) mainly in the periphery, associated with rods and beta (or P or parvocellular cells) mainly in the fovea, associated with cones. A third type of ganglion cell (melanopsin-containing cells), making up a minority of ganglion cells, plays a role in circadian rhythm with projections to the suprachiasmatic nucleus of the hypothalamus which in turn projects to the pineal gland. The M cells and P cells then project to the lateral geniculate nucleus (LGN), where the cell bodies of third order neurons lie.

The journey of these ganglion cell axons is impressively organized as they maintain retinotopographic organization throughout their course. In addition, optic nerve fibers (containing the axons of the ganglion cells) arising from the nasal portion of the retina cross at the optic chiasm to join the contralateral temporal fibers, thus joining fibers from alike visual fields. These joined fibers are now called the optic tract and are destined for the LGN, superior colliculus, pretectal area, SCN of the hypothalamus, and the reticular formation. The LGN is a region located in the dorsal portion of the thalamus. The LGN is constructed of 6 distinct layers from ventral to dorsal. The first two make up the magnocellular layer which receives input from the M cells and thus mainly information from the periphery of the visual field. Layers 3–6 make up the parvocellular layer and receive input from the P cells, or the fovea of the retina.

In what is referred to as the optic radiation, fibers from the LGN making up the geniculocalcarine tract radiate posterolaterally along the lateral ventricles toward the primary visual cortex, again maintaining retinotopic organization. The visual cortex, located at the most posterior aspect of the cerebrum, is divided by a nearly horizontal fissure called the calcarine fissure, which separates the cortex into a superior and inferior portion. The geniculocalcarine tract contains an

upper division with fibers corresponding to the superior retinal quadrants, lower division (Meyer's loop) with fibers corresponding to inferior retinal quadrants, and an intermediate division with fibers corresponding to the macular retina. The upper division relays information to the superior bank of the calcarine fissure and the lower to the inferior bank of the calcarine fissure. The intermediate division projects to the most posterior aspect of the visual cortex and straddles both inferior and superior portions of the calcarine fissure. Through this convoluted pathway from the eye to the back of the brain, visual information has arrived at the primary visual cortex, also called V1, primary visual cortex, or Brodmann's area 17 (Fig. 1). Straddling the calcarine fissure, V1 is located in the midline of the occipital lobes

on either side of the longitudinal fissure. It is here, at the primary visual cortex, that information from both eyes converges onto a single cell for the first time. From here, visual information is further processed through the visual association cortex, or "extrastriate cortex" (Patestas and Gartner 2016).

Function

Visual Cortical Streams of Processing Two streams are often mentioned throughout the literature: the dorsal stream (a.k.a. the "where" stream or magnocellular pathway) and the ventral stream (a.k.a. the "what" stream or parvocellular pathway). The dorsal stream is thought to process information related to movement and spatial localization, while the ventral stream is thought to be involved in object recognition, color processing, and texture/shape identification. Counter-intuitively, the dorsal stream is roughly associated with the LGN M cells (located in the ventral LGN), whereas the ventral stream is roughly associated with the LGN P cells (located in the dorsal LGN).

From V1, the dorsal stream consists of V2, V3, V5/hMT, and V7a. Thus, information flows from the posterior occipital lobe (V1, V2, V3) to the medial temporal area (V5/hMT) and then dorsally to the posterior parietal cortex (7a) in the dorsal pathway. In the ventral stream, information flows again from the posterior occipital lobe (V1, V2) to the more lateral V4 region and ultimately to the inferior temporal cortex. Specific modalities making up the ventral stream include areas involved in the perception of color (V4/V8) located in the ventral occipitotemporal cortex and areas involved in object recognition such as the lateral occipital complex which is further divided into the lateral occipital and posterior fusiform, and ventral occipitotemporal regions, consisting of the fusiform face area and parahippocampal place area (Grill-Spector and Malach 2004). Additionally, studies conducted regarding object handling suggest that certain dorsal foci appear to be activated by object and shape information (Culham et al. 2003; Goodale et al. 1991). We now know that there is some cross-talk between the two streams. Much of what is understood about the

Human Visual Neurobiology, Fig. 1 An overview of the human retino-geniculo-cortical tract. Visual information is carried in a rostro-caudal direction from the retina to the visual cortex. The optic nerves cross in the optic chiasma and then continue caudally as the optic tracts towards the diencephalon. Fibers from the LGN radiate in a rostro-caudal direction towards the primary visual cortex. The visual cortex, located at the most caudal aspect of the cerebrum, is divided by a nearly horizontal fissure called the calcarine fissure, which separates the cortex into a superior and inferior portion

anatomy of the human visual cortex has been discovered using fMRI techniques in addition to the investigation of the macaque visual cortex. As we will see, the complexity of the extrastriate cortex is bewildering and relatively well studied but not yet fully understood. It is here that we can begin to digest the many elements that make up human vision.

Dorsal Stream Functions The famous experiments conducted by Hubel and Wiesel in a cat model demonstrated that particular receptive fields in the visual cortex were oriented horizontally, vertically, or obliquely and that certain areas demonstrated a preference for movement and even direction of movement as evidenced by strength of their firing response. These experiments paved the way for our current understanding of how orientation and movement are processed.

Before Hubel and Wiesel's experiments came to light, the very important work of Kuffler outlined the receptive fields of retinal ganglion cells. In his work, he demonstrated that ganglion cells responded to circular spots of light or darkness at a specific point on the retina. These are now known as "on-center" and "off-center" ganglion cells, respectively. When an on-center cell is stimulated by light, it increases the rate of action potential firing. In contrast, when an off-center cell is stimulated by light, it decreases the rate of action potential firing. However, if the light stimulus is removed, the off-center cell will subsequently increase its activity. Furthermore, he showed that the circumferential area immediately surrounding the receptive field is antagonistic toward the center receptive field's response when stimulated. For example, if the periphery of an on-center cell is stimulated, it has an antagonistic effect which reduces the firing of the on-center cell. As discussed in the anatomy section, this information is then relayed to and modulated at the LGN and ultimately arrives at the primary visual cortex (Kuffler 1953; Purves et al. 2012).

The incoming visual information is thought to undergo hierarchical processing, such that as information moves further through the dorsal stream, the complexity of a stimulus that a cell

will respond to increases. For example, the stationary "point" stimulus which excites an on-center cell in the retina is a much simpler stimulus than the types we will find higher up in the processing stream. However, the varying types of "simple" stimuli are thought to be combined to build the more complex stimuli which start to resemble reality the further into the extrastriate cortex we get.

Hubel and Wiesel characterized cells in different portions of the dorsal stream (V1, V2, and V3) as simple or complex. The most basic of these cells are located in the primary visual cortex (V1) and are called simple cells. Simple cells were found to be selective to orientation and position. In Hubel's experiments, these cells were found to fire strongest when a linear stimulus (such as a bar or edge of light or dark) was at an optimal orientation and remained quiet when the stimulus was oriented 90° to the preferred orientation. Similarly, strength of response was found to depend on position within the visual field. Complex cells, located in V1 and V2, were also found to be selective to orientation. In addition, motion and direction of the motion were found to be important for response optimization. A stimulus moving across the receptive field of a complex cell with specific orientation and directionality produced a sustained response (Hubel and Wiesel 1959; Purves et al. 2012). In humans, separate studies showed that hMT displays direction-selectivity and may not be confined to simple translational movements (Huk et al. 2001; Tootell et al. 1995; Morrone et al. 2000). Interestingly, studies also demonstrated that tracking of motion seems to increase the response of hMT neurons (Buckley et al. 1998; Culham et al. 1998). Furthermore, evidence suggests that a region lateral and anterior to hMT is involved in the perception of biological motion (Grossman et al. 2000). Clearly, the further into the dorsal stream we get, the more complex the information we are dealing with becomes.

As we can begin to see, the synthesis of more complex aspects of motion appears to arise from the summation of information from earlier visual areas. From a collection of on-center or off-center cells, we can construct edges of a specific

orientation. This orientation excites simple cells in V1. A collection of these simple cells with alike orientation at nearby retinotopographic locations forms a translational plane. A stimulus with appropriate orientation that is moving in an appropriate direction through this translational plane excites a complex cell. This type of hierarchical processing is a theme that is not limited to motion processing but one that is thought to occur throughout the visual cortex. As we will see, a similar story unfolds during object recognition.

Ventral Stream Functions

Spatial Frequency The experiments by Hubel and Wiesel demonstrated that primary visual cortical neurons responded to edges and lines, but later research by De Valois demonstrated that these neurons respond even better to sine-wave gratings. A sine-wave grating appears as blurry long parallel rectangles that alternate in light-dark brightness following a sine-wave function. A sine-wave grating is quantified according to its spatial frequency. For a sine-wave grating, spatial frequency is its alternating change in light-dark brightness expressed as cycles per degree of visual angle. Visual angle is the angle measured where two lines drawn from an object meet at the retinal surface. Primary visual cortical neurons react most strongly when a sine-wave grating with a specific spatial frequency is presented in a certain area of the visual field (Carlson 2014; De Valois et al. 1978).

High and low spatial frequencies supply important information about an image. High spatial frequencies are found in smaller sized objects, the features inside larger objects, and the distinct edges of larger objects. High spatial frequency corresponds to abrupt spatial changes in the image such as edges and gives fine detail and configural information. A picture lacking in high spatial frequency will be perceived as blurry and unfocused. Low spatial frequencies correspond to global information about shape such as general orientation and proportions. A picture lacking in low spatial frequency will only have fine details and not general features. Low spatial frequency has been found to be prioritized in the detection of

faces. For these reasons, low spatial frequencies are more necessary for human vision. Low spatial frequency information is supplied by the evolutionarily more ancient magnocellular pathway, of which axons from the LGN terminate in cortical sublayer 4Ca (Carlson 2014; De Valois and De Valois 1988; Awasthi et al. 2011; Bar 2004).

Color Detection

Retinal ganglion cells that are color selective relay signals to the parvocellular and koniocellular layers of the LGN. From there, axons are sent to neurons inside cytochrome oxidase blobs in the primary visual cortex for color analysis. Wong-Riley found these blobs using a stain for cytochrome oxidase, a mitochondrial enzyme that when found in high amounts signifies a cell with a high metabolic rate. Later experiments showed the existence of a polka-dot distribution consisting of dark columns present in layers 2 and 3 and less intense staining in layers 5 and 6 of the primary visual cortex. On cross-sectioning, these columns appeared oval and about 150×200 micrometers in size and separated by 0.5 mm intervals (Wong-Riley 1979).

Two pathways send color signals to the primary visual cortex from the LGN. The axons of projection neurons in the koniocellular and parvocellular layers of the LGN synapse onto specific sets of neurons in the primary visual cortex. The lower sublayer of 4C, called 4C β receives parvocellular input, whereas the superficial layers 2 and 3 receive koniocellular input in a patchy distribution. Experiments on monkeys demonstrated that lesioning the parvocellular layers causes impairment in visual acuity and color vision, indicating this system is used for detecting object shape, color, and size. The parvocellular pathway sends in signals from red (long-wavelength) and green (medium-wavelength) sensitive cones, and the koniocellular pathway sends in signals from blue (short-wavelength) sensitive cones. It is not fully understood why two separate pathways exist for color detection, although it is believed that the koniocellular pathway is evolutionarily more ancient (Purves 2019; Carlson 2014; Wong-Riley 1979; Horton and Hubel 1980; Humphrey and Hendrickson 1980;

Fitzpatrick et al. 1983; Livingstone and Hubel 1987; Hendry and Yoshioka 1994; Chatterjee and Callaway 2003).

The Function of the Organizational Aspects of the Visual Cortex

Retinal Disparity

Depth is important for determining object shape, surface segmentation, and detecting third dimensional aspects. It is perceived in more than one way and can be detected monocularly using cues such as brightness, perspective, occlusion, size, and movement. However, binocular vision allows for a clearer depth perception utilizing stereopsis. This becomes especially essential for controlling fine movements of the hands and fingers such as playing a violin. The majority of primary visual cortical neurons are binocular, meaning that they fire in response to stimuli arising from either the left or right eye. These cells, and most notably those found in a cortical layer receiving magnocellular pathway input, have firing patterns that play a part in depth perception. These binocular neurons fire most intensely when each retina detects an object in a slightly different part of the retina, meaning that they react to retinal disparity, that is, when an object forms an image on slightly different regions of the retina in each eye. This is how the brain forms stereopsis: the left and right retina detects the scenery in a slightly different perspective, and the retinal disparity points to differences in distance between the person and the object being seen (Carlson 2014; Poggio and Poggio 1984).

Binocular integration in the visual system starts in the primary visual cortex at the point where single neurons receive input from both eyes. The amount of input from both eyes differs among neurons in the primary visual cortex; this property is called ocular dominance. When objects are at different distances from the retinas, these binocular neurons will calculate depth based on retinal disparity. If an object is exactly in the plane of fixation, an image is formed at corresponding retinal positions bilaterally. Any images behind the plane of fixation or in front of the plane of fixation will form an image on the two retinas at slightly different areas. Single neurons in the primary visual cortex are selective for a

tight range of these types of retinal disparities. Neurons selective for objects directly in the plane of fixation are referred to as tuned excitatory and tuned inhibitory cells. Neurons selective for objects behind the plane of fixation are called far cells, and neurons in front of the plane of fixation are called near cells. When the depths of more than one object need to be calculated, the retinas must connect all images to perform a global disparity calculation. When the calculation of depth is known for one part of an image, this data is utilized for other parts of the image where information is missing for calculating depth, in a process called disparity capture. By doing so, the calculation of one region of the image will affect calculations for other parts (Kandel et al. 2013).

Modular Organization of the Primary Visual Cortex

The brain is separated into modules, with populations of neurons per module ranging from one-hundred thousand to several million. Modules are heavily interconnected, sending, and receiving signals from one another while performing complex operations. The primary visual cortex is arranged in a visuotopic order such that the visual field is represented along the cortical surface. Every point in the visual field needs to be detected by columns of neurons with varying functional properties in the cortex. From the cortical surface to the underlying white matter, neurons are grouped together tightly into columns which share comparable functional properties including orientation selectivity, spatial frequency, and ocular dominance. Moving along the cortical surface, the change in visuotopic position of receptive fields is slow, yet the change in columns is extremely fast. Any specific point in the visual field is processed by a single modular unit of cortex that analyzes object orientation, direction, color, and depth. A single module contains every possible column and cell-type needed to analyze a single point in the visual field, and this module is repeated hundreds of times to span the entire visual field.

The primary visual cortex is separated into about 2,500 modules, each with around 150,000 cells, nearly 0.5×0.7 mm in size, and containing all 6 layers of cortex. A single module includes a

single orientation hypercolumn: a full 360-degree cycle of orientation columns; a single pair of left and right eye ocular dominance columns; along with a pair of blobs and corresponding interblob regions. A microelectrode placed straight down into an interblob area of the primary visual cortex will demonstrate that every orientation selective cell will fire in response to edges of the same orientation. Neurons in the blobs detect color and low spatial frequencies, and interblob regions demonstrate detection of movement, orientation, retinal disparity, and spatial frequency; but not to color. Blob neurons signal in response to low spatial frequencies and minor variations in brightness. Within the interblob region, spatial frequency detection increases as a function of distance from the blob center region. The farther away from the blob, the higher the spatial frequencies that these neurons detect.

Each module is divided into two halves, each receiving connection from only one eye through the terminations of LGN axons in the ocular dominance columns of layer 4, which are monocular. Axons from layer 4 neurons in neighboring columns form connections with single neurons in all other layers. Cortical layers located directly above and below the center zone of the ocular dominance columns in layer 4 respond to only one eye, whereas at the vertical zone separating the module, neurons recorded from the surface straight down respond equally well to either eye. In-between these zones, areas tangentially recorded along superficial layers show a continuous and gradual change in ocular dominance: from total domination of one eye to equal input from both eyes. Recordings from the surface straight downward demonstrate that neurons have equivalent ocular dominance, except in layer IV which is entirely monocular.

The cortical arrangement into columns decreases the distance necessary for neurons with comparable properties to signal each other and permits them to share signals from separate pathways that relay data regarding specific characteristics of vision. This allows for more efficient use of brain volume and raises calculation speeds. By grouping cells into columns sharing similar properties, the brain can decrease the

number of cells necessary for calculating different characteristics of an image (Carlson 2014; Purves 2019; Kandel et al. 2013; Livingstone and Hubel 1984; Born and Tootell 1991; Edwards et al. 1995).

Evolution of the Human Visual Brain

Visual ability has played a driving role in primate evolution (Cartmill 2012; Barton 2004). Humans share with closely related primate's visual system specializations in foveal vision, visual acuity, binocularity, and trichromatic color vision that have suggested to be related to brain features. Haplorrhine (but probably not strepsirrhine,) primates possess a retinal fovea which has a higher cortical magnification factor (Ross 2004). Primates' high visual acuity has been related to an increased visual surface area, with more neurons (Srinivasan et al. 2015). Neuron density is 2.5 times higher in primate primary visual cortex than in other cortical regions and in other species (Rockel et al. 1980). About half (52%) of the surface area of the cerebral cortex in macaques is primarily visual in function – although human visual cortex is absolutely larger, the proportion is smaller (27%) due to more multimodal association cortex (Van Essen 2004). Thus, the evolution of vision has an important impact on brain size evolution and is linked to the large brain size of primates (Barton 2004). In primates, visual areas are more numerous; this impacts the network structure of the cerebral cortex, with fewer long-range and cross-sensory connections and more short-range connections between visual areas (Meredith and Lomber 2017; Krubitzer 2009; Kaas 1989). The binocular visual field overlap is enlarged in primates, which have relatively convergent eyes (Heesy 2004).

Macaque monkeys (e.g., *Macaca fascicularis* and *Macaca mulatta*) are typically used as models for human vision in research. However, human and macaques share a most recent common ancestor with humans 25 million years ago and it is important to consider that the visual system of humans could show further specializations (Preuss 2004). Some apparent similarities shared between humans and macaque model species – for example, similarities in the lamination of M and

P cells in the LGN – could potentially be due to convergent evolution (de Sousa et al. 2013). Functional neuroimaging in human and macaques has revealed differences in the organization of higher-order visual areas, compared to more similar early visual areas (Orban et al. 2004).

Yet even subcortical structures and early visual areas show species-specific structural variation among *catarrhines* (humans, apes, and catarrhine monkeys). Compared to monkeys, *hominoids* (humans and great apes) show a reduction in a direct parvocellular-geniculate afferent to primary visual cortex layer 4A; this layer is further derived in humans who show a unique mesh-like organization of presumed magnocellular-related cells (Preuss et al. 1999). More research is needed to link specializations of human visual brain structure to cognitive function. Recent work has suggested ecologically relevant visual processing differences between human and chimpanzees such as in shape from shading (Tomonaga 1998) and the face inversion effect (Kret and Tomonaga 2016).

Humans seem to have among the best visual ability of any animal – tied for highest mammalian visual acuity with chimpanzees – and this relates to our ability to process other complex sensory information as well (Heffner and Heffner 1992). The neural demands of visual processing could have led brain features (de Sousa and Proulx 2014) that even in vision's absence relate to high level cognitive functions such as language (Pascual-Leone and Hamilton 2001).

Conclusion

Human visual neuroscience has revealed much about how the eye and the brain work together to process visual information about the environment. It has, more generally, made important revelations about the relationship of brain structure to function. Research on model organisms has revealed that visual neurons respond to specific features in the environment and work together to map features in the visual field. The visual system is a

well-studied model of how sensory systems enable organisms to interact with their environment. This sensory system is particularly important in humans which show specializations in it.

Definition

Human beings are typically characterized as social primates, meaning they live in structured social groups, they communicate and interact with each other, and coordinate their activities around their conspecifics – much like other social primates, such as chimpanzees, bonobos, and gorillas.

Introduction

Forming social ties and living in social groups are of the most fundamental behavioral characteristics of human beings. Humans are frequently referred to as *social animals* to reflect this attribute (Aronson 2018). Living in social groups may have increased the chances of survival and reproduction of our prehistoric ancestors, via facilitating protection from the elements of nature and predators, finding resources (e.g., food, shelter, mates), and caring for offspring, and hence may have been selected for throughout our evolutionary history. The fact that our closest primate relatives, the great apes, also display affiliative behaviors (e.g., group living, social grooming, pair bonds), offer evidence for this conjecture. In the following sections, first the main characteristic of being a social species, cooperation, will be discussed, then different social ties human beings form throughout their life span will be elaborated, and

finally the neurobiological processes underlying human sociality will be briefly deliberated.

Cooperation

Living together in coordinated groups is one of the main defining characteristics of being a social animal. It necessitates a well-developed social cognitive skillset to ensure cooperation. Cooperation requires a complex cascade of mental tasks: The individual needs to be able to recognize other people's separate selves, understand their mental states and intentions, monitor their actual behaviors, keep track of past interactions, and detect deceit. Moreover, they need to calculate the costs and potential benefits of engaging in a cooperative act and restraint own behavior should they decide to cooperate. All these require tremendous cognitive capacity, and reaching this capability has been one of the fundamental challenges for human beings in evolving as a social species. Social primates, including human beings, have overcome this challenge by evolving unusually large brains, which is evident in the correlation between the sizes of social groups and the neocortex, also known as *the social brain hypothesis* (Dunbar 1998). Complex cognitive mechanisms that characterize human beings (e.g., culture, language, theory of mind, sense of morality) are argued to have evolved because they enable the social animal to carry out large-scale cooperation in complex social groups (Tomasello 2014).

Although highly adaptive at the group level, via the optimization of resource utilization and environmental risk management, cooperation is very costly for the individual, both due to the cognitive load mentioned above and in terms of tangible resources, so human beings have evolved to cooperate with conspecifics who are reciprocal in cooperation – who are more likely to be as such when they are among one's own group (Happé et al. 2017). As a result, cooperation is more common within social groups as compared to different social groups. Forming affiliative ties with one's group members serves the function of differentiating in-group from the out-group and hence makes the cooperation decisions more

efficient. Such in-group cooperation is largely automatic and guided by neurochemical systems (Crespi 2016), which makes adaptive sense as this reduces the cost of the taxing cooperate/not cooperate decision and hence allows to maintain interactions with several individuals.

Social Ties Throughout the Life Span

Human beings form many different social ties during their life span. Arguably, the most crucial of these ties is formed in early life with caregivers. The human infant is born altricial, meaning they require extensive care for a long period of time to have a chance at survival. Bowlby (1969/1982), in his seminal attachment theory, argued that the early problem of survival for the immature human infant is solved by the *attachment behavioral system*, an evolutionarily adaptive regulatory device which adjusts proximity to supportive others, i.e., *attachment figures*. This system protects the infant from physical and psychological threats and hence ensures the endurance and procreation of the species. The attachment bond formed with caregivers not only protects the infant from threats, but also teaches them how to affiliate with other people in the world and sets the stage for later social ties.

When infants grow into adults, the same attachment system ensures the formation and sustenance of romantic relationships (i.e., pair bonds) (Hazan and Shaver 1987). Human beings are predominantly socially (but not necessarily sexually) monogamous, meaning they live together with one partner and raise their offspring together. Pair bonds not only increase reproductive success by optimizing fertilization and making childrearing more efficient, but they also have major benefits for the partners. Being in a satisfying romantic relationship has been associated with many positive outcomes, such as happiness and subjective well-being (e.g., Easterlin 2003), and health and longevity (e.g., Robles et al. 2014).

In addition to the social ties in these close relationships, people spend the majority of their life socializing with friends, acquaintances, colleagues, and other in-group members virtually in all cultures. Amounting evidence suggests that

forming and maintaining affiliative ties and feeling belongingness are among the most pervasive psychological needs we have (see Baumeister and Leary 1995).

The Neurobiology of Human Sociality

In both humans and other social species (e.g., prairie voles, titi monkeys), the neuroendocrinological systems are hardwired to form and maintain affiliative ties. Several areas of the brain (e.g., the olfactory system, amygdala, lateral septum) and numerous hormones (e.g., oxytocin, vasopressin) have been linked with social behaviors (see Carter and Keverne (2002) for a review). These brain regions and hormones have crucial roles in motivating the organism to engage in social contact, perform sexual behavior, form pair bonds, care for offspring, cooperate, and regulate pain and stress. Endogenous opioids, which are involved in the brain's reward system, have also been identified to be intricately related to affiliation and bonding processes. This link provides a possible explanation as to how social ties have been experienced as rewarding and hence continued to be carried out. The behavioral or neurobiological responses humans and other social animals give in face of the presence or absence of the conspecifics they form ties with (e.g., physical touch, social grooming, separation distress, increased HPA activation) provide further evidence for the role of social ties in the psychophysiological system.

Conclusion

Living in social groups is a defining feature of human beings. Sharing the burden of ensuring protection, finding resources, and raising offsprings has been evolutionarily advantageous for humans, which led to being a social species. Our behavioral and neurobiological systems are hardwired to ensure we form, maintain, and grow our affiliative ties. Being part of social groups is indeed part of who we are: It increases our chances of survival and reproductive fitness, protects us against stress, and even gives meaning to our existence.

Humans Crawl: Species Atypical Movement

Karl S. Rosengren¹ and John D. Polk²

Synonyms

Gait; Human locomotion

Definitions

Crawling is a form of species atypical movement for humans.

Introduction

Striding, bipedal walking, and endurance running are the hallmark modes of human locomotion, yet humans locomote in a number of different ways. As young infants we start with a system that is more plastic and flexible than it seems, given the relative uniformity of adult forms of locomotion like human bipedalism. This plasticity is evident in the surprising number of different pathways to upright walking (Largo et al. 1985). In this piece we contrast the divergent pathways that humans and their relatively close neighbor, the chimpanzee, take in the ontogeny of adult forms of movement.

Factors Influencing the Ontogeny of Gait

The ontogeny of animal movement is constrained by factors both within and external to the organisms that both limit certain types of actions and facilitate others. These can be described as organismic constraints which are internal to the animal, environmental constraints that are external to the animal and that are relatively consistent across developmental time periods, and task constraints

that pertain to any specific problem that animal is confronted with at a particular time period (Rosengren et al. 2003). At any one time point, these three different types of constraints interact to produce a particular action pattern or behavior.

A change in one constraint can have cascading influence on the emergence of different action patterns. For example, encouragement by health care professionals to have parents have their infants sleep on their backs to prevent sudden infant death syndrome (SIDS: Skadberg et al. 1998) had the unexpected consequence of delaying the onset of motor milestones such as creeping and crawling, in part because supine sleepers do not gain the same experience using their arm and torso muscles necessary for creeping and crawling as prone sleepers (Davis et al. 1998).

For the developing animal, organismic constraints for movement include the timing and pattern of growth, the organization and maturity of the musculoskeletal system, and the motivation to move from one place to another to gain food or obtain shelter. Environmental constraints include the fact that animals on earth are bound by gravity and the structure and characteristics of the surfaces that one can act on (e.g., a relatively flat horizontal ground or vertically rising trees). Task constraints include whether the animal is interested in seeking food, comfort, or safety. Although traditional models of the development of locomotion emphasized that maturation was the main driving force in the ontogeny of human gait, more current approaches emphasize the importance of the developing infants' active exploration of the interaction of these different types of constraints (Rosengren et al. 2003; Thelen 1995).

Gait Ontogeny in Humans

Human infants enter the world with a relatively immature action system that provides ample opportunity to explore the interaction of constraints and in doing so develop a number of species atypical movement patterns. Over the first year of life they acquire the physical strength and coordination to effectively move through the environment. But the ways individual infants

accomplish the act of locomotion is determined by their motivation, physical layout of their home (e.g., does it contain carpeted surfaces or hard tile floors, flat surfaces or stairs), and the goals of their caregivers in promoting exploration or optimizing safety. For this reason, young infants exhibit a wide range of atypical locomotor behaviors to get from one place to another including rolling, shuffling on their bottom, crawling on stomach, crawling on hands and knees, and crawling on hands and feet, prior to the acquisition of upright walking (Largo et al. 1985). The fact that upright gait is relatively uniform as the species-typical pattern of movement suggests that over the course of evolution the different types of constraints have led to a small number (e.g., walking and running) of highly efficient and effective patterns of movement.

Gait Ontogeny in Chimpanzees

For chimpanzees, infants cling to their mothers' fur for safety, transportation, and feeding. These behaviors lead the infants to develop forelimb-dominated, suspensory grasping abilities. Like humans, infant chimpanzees are more variable in their locomotor modes than juveniles or adults, in part because their size permits it and in part because of differences in parenting styles. As offspring size increases (~ 3 years), mothers carry the offspring less frequently, and they transition to quadrupedal knuckle-walking. This species-typical behavior does not become the dominant mode of locomotion until after 5 years, when the chimpanzees are completely independent of their mothers (Sarringhaus et al. 2014).

Conclusion

This cross-species comparison provides evidence that the same three sets of constraints apply to different species. The transition to species-typical posture and locomotion will depend on organismic-, environmental-, and task-specific constraints. The fact that more limited forms of species-typical gait are found in adults suggests

that these constraints interact over the course of development to select for efficient and effective patterns of movement.

Between-group Killing; Feuding; Intergroup Conflict; Intergroup Killing; Warfare; War

Definition

Conflict among human groups or populations, usually of different cultural backgrounds, involves violent interactions. The aggression usually leads to death of part of group members of both sides and to advantages (material or social) to surviving victors.

Introduction

The central aim of evolutionary approaches to the study of intergroup violence is to examine whether between-group violent conflicts and killings are in any way adaptive, and to investigate their evolutionary history. Lethal intergroup conflict among humans during the late Pleistocene and early Holocene is still a controversial subject, with little agreement on its extent (Bowles 2009). It is important to turn to prestate societies, as these are thought to typify the kinds of aggregations that humans belonged to for the great majority of human history. Their study facilitates our understanding of the contexts from which modern behaviors are derived and of those in which human universals had their evolutionary origins. A great deal of interest revolves around illuminating the frequency, intensity, and importance of the types of lethal intergroup killings in small-scale societies such as feuds, raids, massacres, treachery, and warfare. Different hypotheses have been proposed to explain the adaptive value of intergroup conflict, some involving individual-level selection and others group-level selection. Empirical evidences for these hypotheses are reviewed here.

Review

Despite scientific discussions, intergroup killings have been found to occur across a variety of human societies (Guilaine and Zammit 2008). Contrary to the claims of some perspectives, lethal violence between groups did not originate with nation-states. According to archeological data, intergroup killings were already committed by

small-scale societies before the emergence of states. Evidence supporting the occurrence of lethal violence in the past includes Paleolithic, Mesolithic, and Neolithic art in Italy, France, and Spain, as well as osteological evidence, settlement patterns, and weapons retrieved from prehistoric sites across Africa, Eurasia, and North America.

In human subsistence societies, death rates from intergroup aggression are reported to be higher compared to rates of death from intragroup aggression (Heider 1997). The underlying motives for between-group killings in small-scale societies include (Gat 2010): competition for subsistence resources and for mates; contests for prestige and status; retaliation after suffering raids and massacres; elimination of future rivals through pre-emptive attacks; clash of cosmovisions, ideologies, or accusations of supernatural wrongdoing (e.g., witchcraft); and security dilemmas (the actions of one community are misinterpreted as warmongering by another group). Lethal violence in subsistence societies of human hunter-gatherers and farmers occurs in similar average rates (and similar variability in the rates) when compared to those reported for chimpanzee societies. Estimates are considerably high: for instance, in seven subsistence farming societies for which data were compiled, median percentage of deaths accounted for by warfare was 28.5% for men and 6.1% for women (Keeley 1996). These figures are higher than those for hunter-gatherer societies or Western-industrialized societies, especially across recent decades of modern history, although several wars among Western forces in recent decades have resulted in extreme mortality rates that surpass even the upper bounds of war-related mortality estimates for farming societies (e.g., the War of the Triple Alliance between 1864 and 1870). In spite of interpopulational variance in frequency of warfare and mortality rates due to such conflicts, evidence for warfare exists for at least 90–95% of human societies (Keeley 1996), indicating it is a human universal.

A conceptual model for human evolution that has recently gained widespread popularity is the *Ecological Dominance* hypothesis, which claims that modern humans have so mastered the natural environment that the major contemporary sources

of selection are predominantly social. Although this model has much merit, and is related to the “social brain” hypothesis in primatology, it is possible that the case for human autonomy from natural selective pressures has been somewhat overstated. For example, climate change has recently been shown to exert severe selective pressures upon human populations over historical time (Zhang et al. 2007) – e.g., cold historical periods have been associated with elevated rates of intergroup conflict. In such cases, although the more proximal selective pressures behind intergroup conflict and killing might be social (e.g., conflicting views), the more distal selective pressures behind them might be natural (e.g., climate change and reduced resource availability). Game-theoretic models combined with updated information on archeological evidence on causes of death during the late Pleistocene and early Holocene, and with ethnographic and historical reports on hunter-gatherer populations suggest that parochial altruism (i.e., altruism geared toward those of the same group) and intergroup warfare have coevolved during these periods (Bowles 2009). Recent historical analyses in fact support this notion, for instance demonstrating that regions more frequently involved in intergroup warfare throughout Japanese history present higher levels of collectivism (as opposed to individualism or independence; Fernandes et al. 2015). It is important to stress, however, that resource competition is not the only driver of intergroup conflict, and in several human societies studied does not appear to predict warfare.

Comparative studies of hunter-gatherer societies and farmer societies indicate that, although common, material rewards possibly obtained in looting do not appear to be sufficient to explain motivations for individual engagement in group efforts toward warfare (Glowacki and Wrangham 2013). Moreover, capturing individuals who were defeated in battles (thus kept as slaves, for instance) is not a widespread in bands and tribes. On the contrary, when large raids (i.e., massacres) occur, most of the individuals in the attacked group are killed, thus not serving as a direct

socioeconomic boost to victors. Hence, acquiring captives is more of a common practice of chiefdoms or other sociopolitically complex societies. Nevertheless, in those cases where it has been observed, most of the time captives are reproductively active females. Increased status, honor, and prestige appear to be the most common individual benefit for warriors. Increased fertility, be it direct or in the long-term as a result of cumulative combat efforts and recognition, has been observed to be associated with warrior status, such as among the Yanomamo foraging horticulturalists of Venezuela and the Nyangatom nomadic pastoralists of East Africa.

Archeological information permits examining how widespread and prevalent warfare-related deaths were throughout historical periods of human societies. It is worth noting, however, that despite the benefits of relying on the archeological record, its imperfection imposes a limit to the type of inferences that can be drawn. A critical issue stems from the difficulty in distinguishing between violent deaths that resulted from intergroup killings and warfare or from interpersonal attacks within a community. Related to this is the difficulty in ascertaining the number of perpetrators responsible for any given case of violent death. Though these challenges are present, the following sites represent the strongest and most significant examples of likely intergroup warfare in the archeological record (Guilaine and Zammit 2008). The Jebel Sahaba cemetery 117 in Northern Sudan, with an estimated age of 14kya–12kya, offers one of the earliest evidences of seemingly intentional and effective killing between groups, and with a lethality of ~40%. Furthermore, it has been hypothesized that either an increase in population pressure or in ecological distress led to the escalation of competition for resources along the Nile valley, leading to the violence at Jebel Sahaba. Similarly, recent findings from Nataruk, Kenya, provide evidence for intergroup aggression against a band of hunter gatherers in the late Pleistocene–early Holocene (Lahr et al. 2016). However, different for Jebel Sahaba, the remains in Nataruk were not intentionally buried, but rather covered

by the sediment of the lagoon. In Europe many sites exhibit evidence of lethal conflict (Keeley 1996). Furthermore, across archeological sites around the world, the lethality of such encounters has been calculated to be close to that displayed by hunter-gatherers (~23%).

Another line of evidence for the widespread existence of aggressive between-group conflict in human societies comes from cross-cultural and ethnographic analyses. An examination of 11 Amazonian societies found a higher number of deaths as a consequence of between-group conflicts compared to within-group killings (Walker and Bailey 2013). For example, the Ache in Paraguay, as well as the Waorani (precontact) and the Jivaro from Ecuador, experienced considerable levels of lethality (average estimates are 56% for the Waorani, 43% for the Ache, and 42% for the Jivaro). In all 11 societies, males were more likely to be the victims in both between and within-group attacks. Comparatively, only 2% of the aggressors died during the attacks. The intense and escalated competition observed among lowland South American, coupled with (1) comparatively low levels of within-group killing, (2) high genetic differentiation among populations, and (3) small direct individual benefits to warriors, suggest that group selection may be an important force shaping warfare in these societies.

Conclusion

Different lines of study of between-group conflicts emphasize different evolutionary hypotheses for their origin and adaptive value, which involve individual and group selection approaches. However, neither account for the evidence completely, suggesting that complementary explanations employing the integrative multilevel selection theory, rather than relying on one mode of selection, are parsimonious. An adaptationist view of between-group conflict and killing cannot be applied to only a portion of human societies or a portion of human evolutionary history, as comparative ethnographic and archeological data

point to the ubiquity of this phenomenon despite cultural and temporal fluctuations in frequency, specific strategies employed, and death rates.

Definition

Aggressive conflict between individuals within a human group or culture, involving violent interactions, in certain circumstances leading to death of one party and fitness benefits to aggressors.

Introduction

Conflicts of interest and competition are a common feature of social life within groups. Many interindividual altercations lead to escalation of aggression and ultimately to killing. To have an evolutionary understanding of intragroup aggression and killing and assess evidences of adaptive functions, it is important to empirically examine (1) how ubiquitous these phenomena are among human cultures; (2) what social and biological variables explain rates of intragroup aggression and homicide, and if they do so in a predictable way in line with theory; and (3) what consequences these behaviors have.

Review

Registered homicide rates vary greatly among cultures and across time, although they it is a widespread phenomenon in humans (Knauff 1987). While in countries such as Iceland and Japan they are below 0.5 per 100,000 persons per year in recent years, they are more than 100 times more prevalent in the Virgin Islands and Honduras and up to 1000 more prevalent in certain prestate societies. Homicide rates are estimated to have reduced by approximately 20 times in Europe since medieval times (Spierenburg 2008). Some homicides are consequences of individual-level conflicts and altercations and another considerable part are due to gang violence and organized crime. It is important to consider the individual characteristics that may lead to adaptive benefits in lethal aggression, examining the sociodemographics of killing across different sectors of the human population.

Aggression and murder are observed to be a more prevalent behavioral feature of young, unmarried individuals and in those with few resources (such as low socioeconomic status, in modern industrialized societies), especially populations having high levels of inequality, as they have comparatively little to lose by engaging in high-risk behavior such as physical altercations over conflicts of interest (Daly and Wilson 1988). For individuals in such life contexts, expected returns from safe courses of action may be negligible, and relying on delayed benefits may be suboptimal considering socioecological uncertainty; as such, future discounting coupled with aggressive, coercive tactics and elimination of competition may be an adaptive response.

A common reported motive for aggressive and homicidal desires and actions is jealousy and distress over sexual competition (Buss 2000). Even though various behavioral strategies for intrasexual competition exist (involving, e.g., self-promotion, derogation of competitors, mate manipulation, and mate guarding) and various anatomical and physiological features can be argued to be adaptations for intrasexual competition (e.g., penile anatomical characteristics which may facilitate sperm displacement in the female reproductive tract, thus reducing other males'

chances of fertilization), aggressive behavior towards sexual competitors is hypothesized to be an effective strategy for competition. Young men are more likely than individuals in other demographic categories to act on such aggressive desires, suggesting that sexual selection has maximized male competitive prowess during young adulthood. Successfully confronting and attacking other males may not only fend off sexual competition and facilitate mate guarding, but may also permit mate poaching, and increasing status by demonstrating dominance, willingness to take risks, and physical formidability, thus increasing attractiveness.

As such, generally speaking, men are more prone to violence than women. There are various possible nonmutually exclusive explanations for this (Tanha et al. 2010): (1) men are sexually selected to be about one-fifth larger in total body size than women, conferring a greater capacity to deal damage, making violence a more effective means of obtaining goals; (2) men are sexually selected to be anatomically more able to sustain damage in combat (having more muscle and skeletal mass), lowering the costs of violent encounters; and (3) men are sexually selected to possess more cognitive and affective psychological adaptations for violent behavior, making them both more proficient in violent tactics and more predisposed to deploy them.

In a study of six human cultures, 91% of men and 84% of women admitted to having had at least one fantasy of murder (Buss 2000), figures which are more similar than is usually speculated. Although many studies have shown that the frequencies of violent *acts* are also roughly comparable for male aggressing against female intimate partners and female aggressing against male intimate partners, the rates at which these assaults translate into injuries are highly discrepant. This could be because men are more capable of dealing and sustaining damage in physical interpersonal altercations. Thus, such violent interactions more often lead to the death of the female than the male intimate partner. Many special theories have been proposed to explain sex differences in death following intimate partner violence as a result of male sexual jealousy or of other strategic conflicts of interests between the sexes. However, recent

evidence has indicated that the major predictors of between-sex and within-sex interpersonal aggression are virtually identical, rendering these special evolutionary theories somewhat unparsimonious (Figueredo et al. 2018).

It has also been found that in societies where critically important subsistence resources are difficult to defend (such as privately owned livestock) and populations densities are low (which is also typical of herding ecologies), leading to low efficacy of law enforcement (where state authority even exists in principle), a “Culture of Honor” evolves where individuals are selected to take justice into their own hands (Nisbett and Cohen 1996). This system depends upon the maintenance of individual reputations for retributive justice, as this is the only proactive way that vindictive behavior can deter raiding of resources by potential enemies. The maintenance of personal or family “Honor” therefore becomes the psychological mechanism for implementing the implicit threat of violent retribution, by the intentional cultivation of an informal public record for revenge.

The question of how comparable inter-individual aggression and killing are within human populations is also an important one from an evolutionary perspective. Homicide is in no way exclusive to only specific kinds of human cultures or to specific subsistence types (Knauff 1987). Homicide rates in bands and tribal societies exceed those of cities and states. Societies such as the Gebusi in New Guinea, and the Yanomamo in Venezuela, exhibited estimated homicide rates of 683 and 165.9 per 100,000 per year, respectively. These estimates are considerably higher when compared to 2.2 homicides per 100,000 per year in Japan, during 1951–1956 and to 15.1 in the city of Kent, during the thirteenth century. Similarly, societies traditionally considered to exhibit low levels of intragroup conflict such as the !Kung had annual homicide rates of 41.9 between 1920 and 1955. However, it has been contented that these cases may not adequately distinguish between intra- and intergroup killings despite the fact that they have been classified as homicide.

Circumstances and reasons for infanticide are strikingly comparable among human cultures (Daly and Wilson 1988). Although not observed in high rates, filicide is more commonly

committed by parents in life contexts that are not favorable to child rearing and in cases of children illness or deformations, both of which are situations prone to jeopardize parental fitness. Unrelated men most commonly commit infanticide if adulterous conception is suspected. Thus, although extremely distressing, killing of children appears to largely conform to theoretical expectations that would facilitate gene-copying replication, showing signs of adaptation.

The challenges of investigating the archaeological record for evidence of interpersonal violence are greatly reduced compared to those of studying intergroup conflict. Interpersonal violence can be inferred through the evidence of trauma, and injury on skeletal remains such as embedded lithic points, cut marks, and bone fractures (Walker 2001). Additionally, it can be established by a single case exhibiting this evidence. However, a considerable challenge in establishing interpersonal violence is encountered in attempting to correctly distinguish between accidental injury and intentional harm. Another nuance of importance is the recognition that many forms of behavior can be subsumed under the label of interpersonal violence, such as ritualized fighting as a form of conflict resolution, domestic violence, and social execution.

The sizeable quantity and relative completeness of known Neanderthal remains has facilitated analysis into the nature of their numerous injuries. In comparison to a sample of hospital records on fracture injuries, Neanderthals were found to exhibit considerably high incidences of trauma indicative of interindividual aggression (Walker 2001), although part are due to accidents and hunting-related injuries. Similarly, a smaller sample of early human skeletal remains from Africa and the Middle East seems to exhibit a consistent pattern of elevated rates of head trauma and injury (McCall and Shields 2008), like those observed in Neanderthals and modern human assault victims. Further archaeological evidence supports the occurrence of lethal violence during prehistory. For example, in sites such as Grimaldi (27kya-24kya) and San Teodoro (14kya) in Italy, embedded projectiles were found within the remains of juvenile victims.

Finally, ethnographic descriptions have also considered how societies respond after the occurrence of homicide, with responses ranging from indifference to a collective disapproval accompanied by punishment (Boehm 1999). As such, even though it seems that the existence of within-group killing is ubiquitous, societal attitudes toward it may vary somewhat, although they are in no culture positive, as they are in the case of between-group conflicts and warfare. Based on the type of social sanction, killers sometimes prefer to desert the group rather than facing any form of social sanction. Blood money, for example, is the financial restitution to the family of the victim and has been a common practice across prestate societies, such as in Norse cultures during the eighth to tenth centuries. It is worth noting, however, that under some circumstances, societies such as the Hadza, the Alaskan Eskimos, and the Kung resort to executions when other regulatory mechanisms are deemed ineffective. However, due to the risk of retaliation by either kin or allies of the offender, the decision of eliminating the offender is taken collectively, and under some conditions the execution is conducted by the kin of the attacker.

Conclusion

Although cross-cultural variations among modern human societies are observed in terms of homicide rates, sociodemographic predictors and attitudes towards within-group aggression and killing are less variable and more in line with expectations based on evolutionary theory. It is clear that such forms of social interactions are not a product of civilization and are not limited to only a part of human societies, and the evidence strongly supports the notion that within-group killing can be, although it need not always be, an adaptive strategy for competition for reproductive maximization, rather than a dysfunctional or exaggerated outcome of aggression.

Definition

Humor refers to “anything that people say or do that others perceive as funny and tends to make them laugh” (Martin and Ford 2018, p. 3).

Ostracism refers to the exclusion or rejection of persons.

Introduction

Most of us have been ostracized, ignored, or rejected at some point and experienced the hurtful consequences of being ostracized. Humor and laughter might have been one way of excluding us. This entry presents a brief definition of ostracism and its consequences, explains how humor and ostracism are related, and summarizes empirical research about the link between humor, laughter, and ostracism. It concludes with suggestions for future research in this area.

The Relation between Humor, Laughter, and Ostracism

When individuals are ostracized, they are ignored, excluded, or rejected (Williams 2007). Humor and laughter can be ways of ostracising individuals and groups. The term ostracism is based on the Greek word *ostraca*. This is a shard of clay that Athenians used to cast their vote on who should be banished from the community for ten years. Ostracism is pervasive – it can be observed in almost all social species, cultures, institutions, age groups,

and groups of different sizes (Williams 2007). In the literature, the terms “ostracism,” “social exclusion,” and “rejection” are not consistently differentiated and often used interchangeably.

In his review of ostracism research, Williams (2007) describes short-term and long-term consequences of ostracism. Even short episodes of ostracism threaten fundamental needs – namely belonging, self-esteem, control, and meaningful existence. Historically at least, ostracized individuals and groups suffered from negative consequences such as restricted access to resources leading to lower chances for survival and reproduction (Alexander 1986).

Two categories of consequences to these threats of fundamental needs can be distinguished (Williams 2007). Ostracized individuals either show more prosocial thoughts and behaviors (presumably to satisfy their relational needs), or more antisocial thoughts and behaviors (presumably to satisfy their efficacy/existence needs of control and recognition). Longer episodes of ostracism deplete coping resources and can lead to helplessness and depression. Thus, for the ostracized individual, ostracism can have very negative consequences. For the ostracizing group, though, ostracism can have positive consequences, because the group can eliminate unsuitable group members and maintain cohesion.

In his groundbreaking work on humor and ostracism, Alexander (1986) puts forth the basic assumption that humor developed as one form of ostracism. Humor “is a broad, multifaceted term that represents anything that people say or do that others perceive as funny and tends to make them laugh” (Martin and Ford 2018, p. 3). Alexander (1986) regards humor as a status-altering activity. This is corroborated by anecdotal evidence about a literal connection between humor and ostracism in some groups (Williams 1997). The Greenland Eskimos, for example, have joke telling contests to resolve conflicts. The person with the most laughs wins, and the one with the least laughs has to go to exile. Alexander (1986) postulates that ostracizing humor singles out a victim, whereas affiliative humor maintains group cohesion. This hypothesis is supported by detailed

analyses of lab group discussions (Robinson and Smith-Lovin 2001). Humorous comments referring to the self or another group member can undermine cohesion in groups; and humorous comments referring to the group as a whole or to outsiders can increase cohesion.

More recent empirical research has examined the link between humor and ostracism. Two experiments illustrate the negative effects of disparagement humor, e.g., sexist humor, for members of the target group (Ford et al. 2019). Disparagement humor occurs when denigration is disguised as harmless amusement or followed by “just a joke.” Individuals who were exposed to humor disparaging their political in-group perceived a social identity threat resulting in feelings of social exclusion (Ford et al. 2019).

Even observing someone else being ridiculed can affect an individual’s behavior. Janes and Olson (2000) labeled this effect “jeer pressure” and examined it in two experiments. Participants saw videotapes with a speaker either ridiculing another person’s physical and behavioral misfortunes, ridiculing his own misfortunes, or using humor without a specific target. Only those participants who saw how another person had been ridiculed were more conforming and more afraid of failing than participants in the other experimental conditions.

Being ostracized can also influence how individuals appreciate humor from others. More specifically, it can lead to ingratiation and finding even unfunny jokes funny (Sacco et al. 2018). In a lab experiment, participants were either ostracized or included in a virtual ball toss game. They then rated the funniness of target persons who were presented with funny or unfunny jokes. Excluded men, as compared to included men, rated female targets as funnier – even when their jokes were unfunny. No such effect was found for excluded women, though. Thus, humor appreciation may help to assure social affiliation after being ostracized.

Besides humor, laughter can also be perceived as a cue for ostracism (Lackner et al. 2018; Papousek et al. 2014). This is especially true for individuals with gelotophobia, which is a fear of getting laughed at. In an experiment, individuals

with and without gelotophobia heard two insulting statements and laughter while solving arithmetic problems. Laughter was presented as ambiguous and in a personally relevant context involving a social interaction. Thus, participants could perceive laughter as a cue of rejection but did not necessarily need to. Results showed that individuals with gelotophobia showed a “freezing-like” physiological response to laughter as indicated by heart rate deceleration. This reaction implies the perception of social rejection. Heart rates slowed down more and for longer in individuals with gelotophobia than without gelotophobia.

A follow-up study with only healthy individuals provided more support for the assumption that laughter as an ambiguous social signal can be interpreted as a signal for social rejection (Lackner et al. 2018). Regardless of whether participants had experienced social rejection or acceptance, all participants showed a “freezing-like” response after hearing laughter as indicated by sustained heart rate deceleration. This response was even prolonged for participants who had been accepted. The result might imply that participants felt being laughed at in an ambiguous social situation.

To summarize, research corroborates an association between humor and ostracism. However, because humor has a multitude of forms, not all humor is necessarily linked to ostracism. Benign forms of humor such as spontaneous conversational humor and unintentional humor (such as physical or linguistic “accidents”) are probably less closely linked with interindividual processes and outcomes.

Conclusion

Ostracism is pervasive and can have negative consequences. Empirical research supports the link between humor and ostracism that was first proposed by Alexander (1986). Disparagement humor can result in feelings of social exclusion (Ford et al. 2019), and observing someone else as the target of humor can result in conforming more strongly (Janes and Olson 2000) – potentially to

avoid social exclusion. Being ostracized leads to changes in humor appreciation, more specifically in finding unfunny jokes funny (Sacco et al. 2018). Finally, even laughter without humor can be perceived as a cue for ostracism (Lackner et al. 2018; Papousek et al. 2014).

Most research to date has focused on the target perspective, on short-term consequences, and has been experimental in nature – enabling researchers to make claims about cause and effect. To examine the complete picture about humor and ostracism, more research is needed on perpetrators of ostracism and the relationship between target and perpetrator, on long-term consequences, and in field studies.

Humor as sexually selected trait

Introduction

Sense of humor is a sexually attractive trait that is ranked as one of the most desired attributes in a prospective mate. However, men and women are interested in somewhat different qualities of humor when choosing a mate. Women place greater importance on choosing a mate that makes them laugh, while men are more interested in a woman who will laugh at their humor. Sexual selection theory can explain these disparate preferences, and there is abundant evidence to support the view that men and women evolved different psychological adaptations to appreciate and create humor.

Humor as a Sexually Selected Trait

Researchers generally agree that sense of humor is an adaptive trait, though there is no consensus on the nature of the adaptation or the mechanism that explains the evolution of humor (Greengross 2014). One evolutionary explanation that has generated much empirical work is based on sexual selection theory, and the view that humor serves as a mental fitness indicator (Miller 2000). The theory focuses on the asymmetry in reproductive costs for men and women (as with most other mammals), and the fact that women invest more time and energy to care for children. This makes women choosier than men when selecting a mate and drives men to try and advertise mate qualities that would make them more appealing to women. A great sense of humor is hypothesized to serve as such a reliable cue for a high-quality mate, an honest signal of intelligence that underlies genetic quality (low mutation load). This advertisement of high quality humor is similar to the extraverted and colorful peacock's tail, an ornament that functions as a fitness indicator to attract peahens. With humor, choosy women should be attuned to cues of high humor ability in men and be more attracted to men who manifest a great sense of humor, while men should try to allure women with their sense of humor.

Sex Differences in Humor Mate Preferences

Sense of humor is hypothesized to be a product of sexual selection and the differential life-histories of men and women that shaped distinct psychological adaptations. If sexual selection played a role in men's and women's humor mate preferences, we should expect to find sex differences in the way men and women enjoy and use humor. Specifically, women should express more interest in mating with a man who displays a great sense of humor, while men should be more attentive to cues showing that women appreciate their sense of humor, and put less emphasis on women's humor ability. Indeed, several large and cross-cultural studies support the notion that women considered humor to be a more important trait when choosing a mate than men did (e.g., Lippa 2007). Women show a special preference for a man with good humor production ability over a man that appreciated their humor for all relationship types (dating, one-night stand, short- and long-term relationships, and friendship), while men show an overall preference for a woman that would appreciate their humor over a woman that would make them laugh (especially for dating purposes) (Bressler et al. 2006). One study found that the use of humor by an attractive man increased his desirability as a mate for women, for both short- and long-term relationships (Lundy et al. 1998). Other studies that looked at the actual mate choices of men and women uncovered similar trends. When analyzing actual personal dating ads, where people have little incentive to lie about their preferences, researchers found that women desired a humorous partner much more than the opposite (e.g., Wilbur and Campbell 2011).

Sex Differences in Humor Production

Based on sexual selection theory and viewing humor as a fitness indicator, it was hypothesized that women's preference for a humorous mate would foster men to try and make women laugh. It is expected that funny men will be considered desirable as mates, while women's humor ability

should make little difference in how attractive men perceive them. A few lines of research support the view that men and women use and value humor differently. Studies that analyzed natural conversations between men and women in restaurants, shopping malls, sidewalks, and bars found that men were more likely than women to tell jokes and to initiate humor. Men's efforts to make women laugh are quite successful, as evident by the larger amount of laughter displayed by women in response to men, compared to how much men laugh in response to women. Women tend to laugh almost twice as much as men in mixed conversations, and their laughter is mostly in response to men talking (Provine 1993). The larger amount of laughter manifested by women is not just an arbitrary feature, but rather signifies women's sexual interest in men. Men who produce high quality humor are more physically attractive, while women's humor ability makes little difference in how attractive they are to men. In addition, the amount of laughter by women predicts both women's and men's interests in dating each other, while men's laughter does not evoke such interest in dating in either of the sexes (Grammer 1990).

Producing humor does not only make men more attractive to women but can also increase mating success. Individuals with higher humor production ability exhibit greater sexual access to partners of the opposite sex, as measured by actual sexual behaviors. Funny people report earlier age at first intercourse, larger number of sex partners, and having more sex in general, compared to the less funny individuals (Greengross and Miller 2011). These results were true for both men and women; however, the incentives for men to be funny are greater, as women are attracted to funny men but not the opposite. Men therefore are presumed to be more motivated than women to use humor, with the hope of mating with women who find their humor attractive. Further support for the benefits men gain from producing high quality humor comes from a slew of studies showing the men's humor production ability is greater, on average, than those of women, which makes it more likely for men to use humor to attract mates (Greengross and Miller 2011; Mickes et al. 2012).

The allure of having a great sense of humor seems to be true for both short-term and long-term mating. For example, women are more likely to give their phone number to a man, and also find him more attractive, when he is telling jokes to a friend, than to the friend who laughed at the jokes. In addition, spousal humorosity was more important for the marital satisfaction of the wives than the husbands in a cross-cultural study of five countries (Weisfeld et al. 2011).

Conclusion

Both men and women recognize the significance of humor in attracting mates, but they differ in the importance they place on producing and appreciating humor. Women emphasize finding a man who will make them laugh, while men are more interested in a woman that will appreciate their humor and laugh at their jokes. Ample evidence suggests that humor is a sexually dimorphic trait, where women are attracted to men with high humor abilities, while women's sense of humor does little to attract men. Men are more interested in women laughing at their jokes, and women's laughter signals their romantic interest in a man. Men's laughter does not affect how attracted women are to them. A great sense of humor is an attractive trait that translates into mating success, and this is true especially for men, as men are more motivated to create high quality humor and produce better humor than women, on average.

Definition

The production of humor leading to laughter and cheerfulness in others.

Introduction

Humor production and appreciation is a human universal and may have evolved as a species typical adaptation in humans (Greengross and Miller 2008). Across the vast majority of cultures, “a good sense of humor” in a partner is listed off among other seemingly more important traits like intelligence and attraction (Bressler et al. 2006). From an evolutionary perspective, we understand that typical attractive features are thought to be indicative of genetic fitness (i.e., lower mutation load) and thus are considered fitness indicators. Taking that idea a step farther, Miller (2001) explains that there are also *mental* fitness indicators – honest signals to genetic fitness via behavioral interactions with the environment: intelligence, creativity (including artistic and musical ability), and humor. In order for an individual to successfully deliver “good” humor, they must possess intelligence and creativity. Essentially effective humor production requires the coordination of a multitude of other (mental) traits that have underlying genetic quality.

Interestingly, though “a good sense of humor” is generally desired, a few research studies found that males were not necessarily attracted to women that were considered “funny.” In actuality, it seems the way in which males and females used the phrase “good sense of humor” differs. While men only emphasize the importance of a partner’s receptivity to humor, women emphasize both humor production and receptivity equally; the difference lies in the attraction to humor production (Bressler et al. 2006). Essentially, from this view, humor production is a mental fitness indicator and humor receptivity/appreciation signals sexual interest.

This interest though seems to be contingent on the way and *type* of humor being produced. Typically, when discussing humor, the first thing that comes to mind are jokes with a distinct set-up and punch lines – yet structured jokes only make up 10%–15% of laughter in typical social contexts

(Greengross and Miller 2008). Surprisingly, most laughter is derived from individuals reacting to spontaneous stimuli within the environment during informal conversations. An ability to react to these situations quickly and respond in a humorous manner hints to the recruitment of a number of processes (like intelligence, creativity, and an assessment of social context) to produce a response quickly. Because of the acuity of these jokes, replication does often not yield the same response due to the change in (social) context.

Humor Styles

From a mating relevant perspective, two specific types of humor forms stand out: self- and other-deprecating humor. Self-deprecating humor takes the form of “making fun of oneself” for perceived deficits in various traits like intelligence or physical attractiveness. Typically this type of humor is found in mating contexts: during courtship or in mated-pairs when a partner is trying to relieve tension after a disagreement (Greengross and Miller 2008). That being said, it can be considered somewhat risky due to the fact that it may actually draw attention to true flaws in an individual. Other-deprecating humor (often referred to as “dissing”) usually arises between potential rivals when the perceived deficits in another individual’s traits (i.e., intelligence, status, attractiveness) are essentially mocked. This form of humor may be taken as more of an insult than a joke, resulting in possible retaliation from the individual being “dissed.” Both forms of humor present potential risks if not delivered properly. The costly signaling theory explains that if an individual can successfully execute a “risky” or potentially costly behavior, they may be considered more attractive. Unsurprisingly, self-deprecating humor is considered more attractive than other-deprecating humor when used by high-status long-term mates.

Conclusion

Humor is an incredibly salient part of our lives: In order to be pulled off correctly, it must be

coordinated by many complex systems, yet it plays an incredibly important role in communicating with potential mates or partners. Our desire for humor (delivered appropriately) speaks to the complexity of our evolutionary mating systems.

Definition

Hunter-gatherer societies (HGS) are a type of society whose subsistence needs are met by gathering wild plant resources, hunting wild game, and fishing, without reliance on agriculture or domesticated animals except for dogs (Lee and Daly 1999).

Introduction

Throughout the Pleistocene, HGS spread to occupy nearly every habitable corner on the planet and locally adapted to a diverse array of ecosystems. For approximately 95% of the time span during which human evolution occurred, people lived in HGS, that is, from the emergence of *Homo sapiens* until approximately 10,000 years ago (Lee and Daly 1999). Therefore, there is potential to greatly inform our understanding of human evolution by studying the social dynamics and other patterns that characterize modern HGS since their contexts are the

most similar socioecological contexts which exist today to which humans have had the most time to adapt. Given this argument, it should be recognized that extant HGS are not exact models of Pleistocene HGS, but they are the best ethnographic models available and are therefore still useful. This entry will summarize important core aspects of HGS. Attention will be directed toward what could be conceptualized as modal patterns of HGS in the areas of social organization and cooperation (Hill et al. 2009, 2011; Mathew et al. 2013).

Hunter-gatherers live in social groups characterized by fission-fusion dynamics, i.e., people freely travel between subgroups in their daily foraging activities and between other bands seasonally or at much longer timescales (Lee and Daly 1999). Hunter-gatherer bands are therefore comprised of a flexible mix of individuals, with important social bonds among individuals within and between bands. Individuals co-residing in bands are connected by close and distant ties of genetic and affinal kinship, while some individuals in a band are not related at all. For example, among the !Kung and Ache, approximately 25% of individuals within a band are not related in any way (Hill et al. 2011). While, band membership is so flexible that individuals in HGS are likely to encounter many individuals during their lifetime. For the Hadza and Ache, data show that, on average, adults interact with more than 300 other same-sex adults during their lives (Hill et al. 2014).

HGS are broadly egalitarian (Lee and Daly 1999). There are no formally defined positions of social power to which individuals are ascribed by birth or with which they can act unilaterally against the wide interests of their peers (Boehm 1999). Despite this, status dynamics and leadership roles are still relevant but are muted in contrast to more complexly organized societies. Leadership is often context-specific and achieved by those who exhibit qualities that facilitate the coordinate and logistics of achieving group goals, such as knowledge, experience, intelligence, etc. (Glowacki and von Rueden 2015; Hooper et al. 2010). Achieving higher status is associated with higher

measures of biological fitness across small-scale societies independent of subsistence strategy, though the effect size of this association is weaker among humans than in primates generally (von Rueden and Jaeggi 2016). While material wealth stratification is minimal or nonexistent among most HGS, disparities are observed in access to important social relationships, i.e., relational wealth, which have a greater impact on a family's well-being than on material or embodied wealth (Smith et al. 2010). Additionally, relational wealth is moderately heritable across generations, as is the case for Ju/'hoansi *hxaro* partnerships, which importantly assists individuals in surviving particular periods of intensified need and finding marriage partners (Smith et al. 2010).

HGS are also extremely cooperative (Mathew et al. 2013). They universally and intensively share food. Mathew and colleagues summarize that detailed data from three HGS indicates that major pathways of net food transfers occur from husbands to wives, from parents to dependent offspring, and to currently breeding mates from nonreproductive adults (2013). These pathways being the major features of human family organization and reproduction; pair bonded males and females who cooperate in reproduction by dividing specialization in productive strategies by sex; intergenerational resource flows from older to younger; and cooperative relationships among kin and unrelated individuals to reduce daily food variance and provide other forms of childcare (Kaplan et al. 2007). HGS also notably coordinate production activities in varying instances of large-scale collective action, e.g., building game drives, large fish weirs, and coalition formation in warfare (Allen and Jones 2014; Boyd and Silk 2014).

Hunter-Gatherer Societies as Sources of Data in Evolutionary Psychology

Darcia Narvaez

Department of Psychology, University of Notre Dame, Notre Dame, IN, USA

Synonyms

Immediate-return societies; Nomadic foragers; Small-band hunter-gatherers

Definition

Small-band hunter-gatherer societies or nomadic foragers are “immediate-return” societies who lack significant possessions, do not cultivate plants, domesticate animals, or hoard food, in contrast to delayed-return societies who do one or more of these things.

Introduction

Often, people confuse nonmodern types of societies as if they were all the same. The differences among small-band hunter-gatherers, complex hunter-gatherers, tribes, and chiefdoms are quite important. All but the first cultivate plants or domesticate animals, activities that lead to hierarchy and inequality, and typically represent sedentary, patriarchal societies prone to violent management of conflict.

Nomadic foragers are distinctive. Nomadic foraging bands are similar in structure wherever they have been found all over the world (Lee and Daly 2005). They represent the type of society in which humanity spent 99% of its history before agricultural settlement. Nomadic foraging is not merely a subsistence mode but also represents a long-term evolutionary inheritance of social patterns based on equality, cooperation, and partnership. Many groups have persisted to the present day. The collected set of ethnographies from

nomadic foraging societies are relevant to understanding humanity's psychological and social evolutionary legacies (e.g., Kelly 1995; Lee and Daly 2005; Woodburn 1982).

Which Hunter-Gatherers?

Nomadic foraging bands have been ethnographically described for all major world regions. Some bands still exist but they have become increasingly rare in recent centuries and decades due to ecological destruction of their habitats, land grabs, epidemics, and even extermination campaigns. The data from which this discussion is drawn include individual ethnographies (for review see Lee and Daly 2005), studies that systematically sample nomadic forager societies (e.g., Fry 2006; Fry and Söderberg 2013) and comparative forager studies (e.g., Kelly 1995; Woodburn 1982). The focus is on the recurring patterns across foraging societies, from different continents and habitats.

There are several reasons that examining data from mobile groups is useful for social science. First, as noted, most of humanity's evolutionary past was spent in this kind of nomadic foraging society. Thus we can take it as not just an economic subsistence form of life but a stable form of living. Fry (2006) summarized the recurring demographic features reported for dozens of mobile forager societies worldwide. Recurring patterns include small size (25–50 individuals on average) and low population densities, mobility with flexibility and fluctuations in group composition, and interconnections among bands (especially among those that speak the same or similar languages). Territory is loosely defined among groups. Bilateral systems of descent (maternal and paternal) are emphasized.

Second, all over the world nomadic foragers show recurring patterns of behavior and orientations. Nomadic foraging data offers a glimpse into multiple baselines for human societies: (1) they provide humanity's evolved nest to their young; (2) they demonstrate similar cultures and personalities which likely are related to evolved nest provision, including (3) alternative ways of dealing with

conflict; (4) they display a human nature and worldview distinctive from the modern.

The Evolved Nest

Evolutionary systems theory identifies humanity's multiple evolutionary inheritances, which includes genes but also a developmental niche for the young (Oyama 2000). Nomadic foragers provide the evolved niche, which is similar to that of social mammals who emerged over 30 million years ago (Konner 2005). As for all animals, the human nest matches up with the maturational schedule of the young, shaping the wellbeing and nature of offspring through ongoing constructive interactionism. Nomadic foraging data provide a window on the evolved nest and its effects (aka, hunter-gatherer childhood model, Konner 2005). The human nest has been described by anthropologists as a set of recurring patterns among nomadic foragers (Hewlett and Lamb 2005). For young children, the evolved nest includes soothing perinatal experiences (no separation of baby from mother, no painful procedures); responsiveness to infant needs to prevent distress; extensive on-request breastfeeding (2–8 years; 4 years on average); extensive positive (no negative) touch and holding; positive climate and social support for the mother, the child, and the dyad, including multiple responsive familiar caregivers; and self-directed social play. Transdisciplinary studies demonstrate that each of these nest components has measurable neurobiological effects on the child's personality and trajectory for health, wellbeing, and sociality (e.g., Narvaez et al. 2013). A supportive community nest continues past early childhood as can be surmised by the characteristics of flexible communalism described below. In adulthood, nomadic foragers demonstrate similar cultures and personalities which likely are due to similar early life experiences or evolved nest provision.

Culture and Personality

What kind of cultural patterns do the nomadic foraging data show? The data show a human predilection for peaceful living through fostering prosocial behavior, using nonviolent rather than

violent conflict management approaches, including a lack of warfare (Fry 2006). They emphasize cooperation with high egalitarianism, including between genders. Hunting large game is primarily a male activity and gathering primarily a female activity, though these are not exclusive, and each group makes decisions for their realms of activity. There is minimal leadership and no overarching authority within or among groups; in fact they eschew authoritarian leadership. Individuals are highly autonomous while highly communal. Group decision making is by consensus. There is little material property and minimal private ownership of resources. Generosity and reciprocal sharing are expected within and between groups. Band members practice sexual freedom, tend to find spouses in other groups, and can change partners when so desired. Multilocality, rather than patrilocal, is typical among mobile hunter-gatherers (Dyble et al. 2015, p. 798).

What values do they exhibit? Reciprocity of generosity and sharing are expected within and between groups, even those at some distance. No one goes hungry unless all do. The ties of friendship, kinship, marriage, and gift exchange bind individuals and groups together. Landscape resources are shared. This may be especially important because of the fact that groups are ephemeral – membership is always changing in a fission-fusion pattern. In fact, it is speculated that because of evolutionary pressures “co-residence with unrelated individuals set the selection environment for the evolution of hypercooperation and prosociality. . . . This social system may have allowed hunter-gatherers to extend their social networks, buffering environmental risk and promoting levels of information exchange required for cumulative culture” (Dyble et al. 2015, p. 798). Also valued are humility, respectful behavior, and nonaggression (Boehm 1999; Fry 2006; Woodburn 1982). They live leisurely with limited wants and self-restraint. Overall, they display a partnership orientation to social life, characterized by egalitarianism and respect for individual autonomy but also high communalism.

How are these values cultivated and enforced? The evolved nest, described earlier, is the way to establish self-regulation and

sociality. As they grow up, children observe and imitate the typical ways to interact which include self-restraint, patience, and helpfulness. In everyday life, conversation and banter are used to keep people in line. Prosociality is expected but rewarded with reputation. On the other hand, rough humor is used to minimize the ego inflation of a successful hunter or of someone who is demonstrating greed or is less than generous. In extreme cases, group members may expel (thief; regular troublemaker) or even execute (recidivist killers) offenders.

Dealing with Conflict

One of the most common mistaken assumptions about humanity’s past regards aggression. Nomadic forager data shed light on humanity’s predilection for violence. From nomadic forager data, we can surmise that our ancestors tended to avoid lethal aggression, favored nonviolent cooperation and avoidance during conflict, and used social control mechanisms to maintain a peaceful social life (Fry 2006). Nonviolent conflict resolution includes such techniques as avoidance (physical or emotional), toleration, negotiation, and settlement (ibid). The typical response among foragers is to walk away, foment a discussion, or enter into group contests such as song duels or wrestling. Disputes are typically personal (e.g., two jealous men), and sometimes lead to homicide but most often do not.

With the definition of warfare as *lethal aggression between different communities*, war is a highly rare occurrence among foragers according to extensive analysis (Fry and Söderberg 2013). It must be remembered that foragers have few possessions to fight about, egalitarianism is the norm, population density is low, and there are no military leaders. At the same time, reciprocal exchange practices and ties of kinship and friendship are very strong. It is the latter that increase survival challenges.

Human Nature and Worldview

Nomadic foraging data offer a glimpse into human capacities of development and offer a glimpse into the type of worldview that develops in ancestral conditions of living close to the earth

with basic needs met through the evolved nest and ongoing social support.

Nomadic foraging data offer a contrast to the view of human nature as “economic man” – an acquisitive, calculating, and competitive creature always looking for self-advantage. Along with selfish exploitation, economic theory assumes scarcity in the world and that some will be rich and others poor; work and production, at the expense of leisure, are necessary to eat. These features are contrary to nomadic foraging data where generosity is a dominant value, the world is considered to be full of abundance; work and socializing go together; and no one is coerced to do anything in order to share in the group’s food. Following nature’s gift economy of giving and taking, nomadic foragers practice communal sharing, whether of food or possessions.

Conclusion

Nomadic foraging data have often been ignored, minimized, or collapsed into prehistory, perhaps because they challenge received views of human prehistory and human nature. The data challenge views of human nature as selfish, aggressive, and competitive. In contrast to modern views of humanity and its past, nomadic foragers are fiercely egalitarian, even among genders and ages, with high autonomy and communality and an emphasis on generosity. The social patterns shared across mobile societies include reciprocal social networks across vast distances, peaceful exchange, and restraint in conflict resolution.

Nomadic foraging was the form of living for all humanity until recent millennia. As it is the original form of social life, nomadic foraging represents the social and developmental circumstances reflective of humanity’s evolution. Data from societies that live largely like humanity’s 99% allows researchers a glimpse into deep history. Similar features occur among widely disparate mobile foragers around the world, suggesting a stable form of social organization. Comparative studies with moderns, whose characteristics represent civilization’s effects, can be informative

about how much humans are shaped by early experience and by social lifestyles.

[High blood pressure](#); [Hyperpiesia](#)

Definition

A medical condition in which arterial blood pressure remains abnormally elevated, classically >140/90 mmHg.

Introduction

The development of a maladaptive health disorder may seem counterintuitive to the evolution and fitness of a species; however, pathologies such as hypertension are the result of a biological response to inadequate environments that may have been in favor of survival for previous generations.

Blood Pressure

All organ systems within the body receive energy and oxygen via blood transportation; in larger animals and humans, this transportation requires a significant vascular system to deliver these nutrients to the furthest organs and tissues (Weder 2007). The strength of the blood pressing against arterial walls is defined as blood pressure, and this pressure rises and falls with the heart's synchronous pumping as it is forced through the cardiovascular system. Blood pressure is measured at its maximum, during contraction of the heart (systolic), and at its minimum, the resting state between two heartbeats (diastolic), and is presented as a ratio measured in units of millimeters of mercury (mmHg). Normotensive or normal blood pressure is defined as 120/80 mmHg or lower (Hypertension Canada 2015; Whelton et al. 2018). The volume of the blood being pumped through this system affects the blood pressure, with increased volume forcing excess cardiac output. Two salts, sodium and potassium, are required in a balanced state to stimulate the kidneys to remove excess water from the body; when sodium is present in excess, the ability of the kidneys to remove water is inhibited and plasma volume increases, forcing blood pressure to increase, which may develop into the health disorder, hypertension.

Hypertension

Hypertension develops in response to extended periods of stress, whereby the body attempts to adapt through increased energy consumption or, the other way around, stress comes in the form of

excess energy input and the body has an incapacity to utilize the abundant resources. Stress can be defined as anything that poses a threat to the health or survival of an organism, such as bacterial infections, inadequate nutrient intake, injury, or even mental trauma. Many organisms, including humans, are often driven to increase available energy to fuel the metabolic demand of dealing with a stressful event (Pettit and DeBarr 2011; Torres and Nowson 2007). Chronic stress can lead to increased stores of glucose and/or sodium, increasing risk of a number of disorders, including hypertension. The classical diagnosis of hypertension is repeated measures of blood pressure greater than 140/90 mmHg; however, some medical professionals are treating patients with measurements greater than 130/80 mmHg (Daskalopoulou et al. 2018). Short-term high blood pressure can be harmless; however, chronically it has been linked to a cascade of health issues such as cardiovascular diseases, stroke, vision loss, dementia, and metabolic syndrome.

Thrifty Gene and Salt Hypotheses

A promising concept was developed in 1962 by James Neel, named the thrifty gene hypothesis, which predicted diabetes and obesity were diseases that have developed as a survival adaptation, a remnant of the early evolution of the human species. Early humans were faced with famine, immune threats, and disease. The thrifty gene hypothesis argues that for early ancestors who were able to retain the most out of consumed nutrients, a blood pressure sensitivity would increase their chances of survival by maintaining normotension during low-sodium conditions. These ancestors would pass along their genotype to their offspring, propagating a line of humans suited for conservation of nutrients in times of deficit. As noted, sodium consumption plays a significant role in blood pressure regulation, and Gleibermann (1973) proposed a sodium hypothesis that describes a drive by our ancestors who lived in hot, arid climates, to consume salt to replenish loss from sweat. The readily available, abundant, and nutrient-rich foods in industrialized nations render these proposed evolutionary

genotypes maladaptive, rather than efficient, leading to the development of hypertension and other metabolic disorders (Weder 2007).

These theories have been met with criticism over the past few decades, predominantly over genotypes and population studies. Gosling et al. (2015) argues that, during times of nutritional abundance and deficit, these theories do not hold true for Pacific Island populations, noted to be the exemplary model for the thrifty gene hypothesis. A lack of genetic markers linking diseases to metabolic disorders, Gosling continues that the hypothesis has failed to provide sufficient evidence in its current definition. Different conceptions of the thrifty gene hypothesis, however, are presently driving research in the growing field of epigenetics and fetal programming.

Barker Hypothesis

In 1992, Hales and Barker devised the thrifty phenotype or Barker hypothesis which stipulates that stress in the prenatal environment correlates to the expression or inhibition of genes linked the metabolic consumption. This influences the physiology and metabolism of the fetus through permanent changes in transcription factors, a process termed fetal programming. During significant acute or chronic stress, steroidal hormones called glucocorticoids are released into the circulatory system from the mother, in high concentrations, and are able to overcome an enzymatic placental barrier that usually suppresses the passage of hormones to the fetus (Seckl and Holmes 2007). Infection, injury, or lack of adequate nutrition during pregnancy all present either acute or chronic stress states that can lead to increased levels of circulatory hormones during critical and sensitive periods of fetal growth. Glucocorticoids can inactivate or silence genes that are sensitive to metabolism, predisposing offspring to hypertension when faced with nutrient abundance or stress of their own. Research involving both humans, such as Holocaust survivors, and nonhuman animals currently supports this hypothesis providing evidence of links between early-life stress, glucocorticoids, and hypertension (Keinan-Boker et al. 2015; Nguyen et al. 2015).

Conclusion

Adaptation to novel environments promotes the survival of a species; however, total adaption can produce complications when environmental conditions change (Weder 2007). Humans have adapted to environments deficient (or at least lower) in nutritional support and, as such, are now faced with current health challenges linked to abundant resources. The correlation between the availability of nutrients and the presence of early-life stress suggests that the fetus is provided with information about its probable environment; the Barker hypothesis claims maternal nutrition and the presence of hormones adjust the phenotype through silencing or activation of genes to enhance the fetus' ability for survival. If the fetus were born in a nutrient-deficient environment, the sensitivity to dietary sodium and other nutrients would enhance available energy and cardiovascular circulation required to deal with stress; conversely, this phenotype may lead to the development of a number of health disorders, such as hypertension.

Definition

Imitation in economics and the social sciences is the process by which individuals adopt the strategies and practices of others. Typically we imagine that it is success that is imitated rather than failure.

Introduction

Imitation plays a key role in the economic study of competition, innovation, and evolution: the imitation of good ideas serves as a crucial way in which those ideas spread throughout a population. A key theme in the literature is that imitation improves economies and tends to foster efficiency. Imitation, however, bootstraps off of innovation: without new ideas to imitate stagnation is likely to result.

Three Types of Imitation

There are three broad strands of literature in economics studying imitation. The first is the role of imitation in competitive economies. The second is the role of imitation in pushing the process of innovation and growth. The third is the role of imitation in determining long-run outcomes in evolutionary economies. In all three cases, imitation serves a positive role in advancing economic progress.

Competition

Competitive equilibrium requires that firms maximize their profits. In a long oral tradition, firms were thought to do so by dynamically imitating the policies of rival firms rather than statically “optimizing.” On the one hand, firms innovate – try new pricing and production policies, combine inputs in new ways and with new production processes. On the other hand, they adopt practices of other firms which seem to be successful.

Some of the earliest work in economics on imitation is the examination of how stochastic imitation combined with a degree of innovation can lead to competitive equilibrium – in effect verifying the earlier oral tradition. The classical paper is that of Winter (1971) who studied a Markov model of evolution in an economy with gross substitutes and shows that indeed convergence to competitive equilibrium is obtained. An element of innovation – the innovating remnant in the title – is needed to make sure that eventually good production plans are discovered. Once discovered they are then spread by imitation leading to competitive equilibrium and an efficient production plan and allocation.

Winter’s paper is very advanced for its time, using as it does a stochastic Markov model similar to those that only became widespread twenty or so years later. It provides a much more compelling account of convergence to competitive equilibrium than the deterministic tatonnement and non-tatonnement models of price adjustment that were widely used at the time.

The early literature on imitation, innovation, and competition is well reviewed in the Nelson and Winter (1977) survey which also reviews some of the empirical literature at that time on the importance of imitation. It covers also their own work simulating the process of innovation and imitation.

Schumpeterian Competition

Schumpeter (1942) focused not on static competitive equilibrium but rather on dynamic competition resulting in the generation of new ideas. In this account, imitation is destructive of the profit of existing ideas: this on the one hand makes it less desirable to generate new ideas as profit will

be lost to imitators, but on the other hand makes it essential in order to gain a short-term monopoly by generating new ideas. In this account, imitation forces firms to run faster to stay ahead.

This idea first appears in the literature on patent races such as Fudenberg et al. (1983). There firms engage in a contest to see who can get the monopoly thereby shutting out the competitors. Such models can lead to “excess” innovation.

This Schumpeterian idea is picked up on and plays a key role in some modern theories of innovation, most notably in Grossman and Helpman (1991) and in Aghion and Howitt (1992). Although different in details, both of these theories focus on imperfect competition and quality ladders. That is production may be carried out with different technologies organized on a ladder with lower cost more productive technologies higher on the ladder. Firms move up the ladder either by innovating and discovering a new step or by imitating another firm higher up on the ladder. In the simplest version, an innovating firm keeps its place on the top of the ladder for some fixed number of periods after which imitators enter the rung and drive profits to zero. On the one hand, the presence of imitators takes some of the profit out of innovating; on the other hand, it provides incentive to innovate as only innovation can provide short-term monopoly profit.

These models with their simple imperfect competition point to intellectual property – patents – as a key incentive to innovate. Boldrin and Levine (2004) observing that empirically patents seem to have little to do with innovation (see Boldrin and Levine 2008 for a review of the evidence) contest this point of view. They observe that the presence of imitators – of copiers even – does not drive profit to zero as a matter of theory. Imitators must pay for a product to imitate and imitation takes time. Moreover, innovators have a number of methods of generating profits such as the complementary sales of expertise and services – the driving force in open source software – with which to profit from their ideas. Hence imperfect competition in general and patents in particular are by no means necessary to generate innovation and growth – it is the movement up the ladder that is key.

This connection between imitation and growth is further reinforced when we recognize that R&D not only is needed in order to innovate but in order to imitate. For example, Griffith et al. (2004) show that R&D is essential in order to imitate existing ideas. This perhaps is not surprising: one who is not actively doing research in an area is unlikely to quickly appreciate the breakthrough of others working in the area. A biochemical formula will mean little to someone who is not a biochemist; we are likely to get better service for our software from the creators than from people who simply copied the code verbatim, and so forth.

This connection is also relevant in the literature on user innovation. Von Hippel (2005), for example, makes the point that it is users of products and imitators who often improve those products. Here imitators also improve upon the original. One of the fascinating things is the “not invented here” syndrome so that producers of products often attribute to themselves improvements that originated either with users or imitators.

Empirically theories of user innovation and competition such as Boldrin and Levine (2002) better match the data than Schumpeterian models. We see this in empirical work of Irwin and Klenow (1994) for example. Their study of memory chips is particularly useful as the quality ladder is clearly defined moving as it does by factors of four. The key fact is that production of a particular quality does not jump up instantaneously but ramps up gradually – long after imitation has taken place – and that a new quality is only introduced when the stock of the old one is fairly large. Each old vintage is phased out gradually as the new one is introduced. The price data shows that the price of each vintage of chip falls roughly exponentially over the product cycle – meaning that the incentive to introduce the next generation chip keeps increasing. Evidence suggests this is the usual pattern in most industries. It makes the point: why introduce a new product if the old one is still doing so well? Rather innovation waits until the market is relatively satiated and there is reason to introduce a new product.

Evolution

In the original work on evolutionary game theory in Kandori et al. (1993) and Young (1993) innovation was central and imitation not present. One conclusion from this literature is that evolution selects not for efficiency but trades off efficiency against a measure of the risk from coordination failure. The subsequent literature shows that when imitation is present along with innovation there is a stronger tendency toward efficiency – reinforcing the conclusions of Winter about competition and Boldrin and Levine about growth.

The contrast between models used by economists to study learning and biologists to study evolution highlights the role of imitation. Traditionally learning models in economics have focused on best response dynamics in which players attempt to do the best they can relative to how other people in the population are playing. This is rather different than biological models of evolution in which the number of offspring a population can produce is greater in a larger population all else equal. However, when imitation is introduced into economic models, dynamics more similar to biological models results.

Consider first how biological models work. Central to biological models of evolution is the replicator dynamic. This asserts that ideas (or organisms) reproduce based not only on how much utility or fitness they provide, but also on their current level of success as measured by their population. In biology, this reflects the fact that a larger population will have more offspring than a smaller population all else equal.

What happens when imitation is introduced into the economic setting of ideas rather than organisms? Schlag (1999) showed how imitation in an economic setting can lead to a dynamic more like the replicator dynamic of biology than the best response dynamic of traditional economic theory. If players they acquire information through imitation then the chances of meeting a player playing a better strategy depend on how many of those other players there are. This means that more popular strategies are more likely to spread all else equal.

One of the peculiar and unattractive features of the replicator dynamic is that it can get stuck – if

everyone is doing the same thing, no matter how stupid, then the system cannot move. If there is only imitation this makes perfectly good sense: if the population is homogeneous there is nobody to imitate. Hence we need some degree of innovation. Imitation alone is never enough – and this is characteristic of all types of economic models.

It is natural to combine the random innovation model of Kandori et al. (1993) and Young (1993) with a model of imitation. This program is carried out in Levine and Pesendorfer (2007) who model a process in which imitation more common than innovation, but in which innovation is present as well. They show in this case that stochastic stability is determined by the outcome of pairwise contests. This favors relatively efficient outcomes – for example, if strategies can identify themselves to each other.

This tendency toward efficiency can be found in other strands of the economics literature. Ellison and Fudenberg (1993, 1995) study how rules of thumb for imitation evolve and find also that there is a tendency towards efficient outcomes.

A particularly clean example of how imitation and evolution lead to efficiency can be found in Ely (2002). Ely studies a model in which there are different locations. Innovation takes place at different locations and imitation has the form of moving to a particular location and adopting the social convention there. Naturally people move to successful locations and unsuccessful – inefficient – locations gradually lose population to the successful – efficient locations. In the long run, the outcome is fully efficient.

Conclusion

Economists have studied a broad range of models where imitation plays a crucial role in spreading ideas. In dynamic theories of competition, imitation plays a key role in establishing competitiveness and efficiency. In the theory of growth and development, imitation may drive down profits from existing ideas, but by doing so creates incentives to create new ideas. In evolutionary game theory, imitation spreads good ideas pushing

toward more efficient outcomes. In all cases, it is the combination of imitation and innovation that results in good economic outcomes.

Definition

Using someone as a model for one's own actions.

Introduction

Scientific interest in imitation and mimicry in the animal kingdom goes back at least to the times of Darwin. The debate on the cognitive aspects of imitation, however, is more recent. Influenced by serial sensory-motor, stimulus-response models of perception-action coupling, the cognitive mechanisms that make imitation possible were initially framed as the “correspondence problem.” That is, how does retino-centric, visual information about the actions of other people get translated in body-centered information that the imitator uses to copy the observed action? The correspondence problem, and the model of

perception-action coupling that inspires it, obviously assumes no shared representations (or codes) between perceptual inputs and motor outputs. A longtime alternative model to the sensory-motor model of perception-action coupling is the ideomotor model (Hommel et al. 2001). This model assumes at least some level of shared representations between perception and action, thus making the correspondence problem fundamentally irrelevant. The ideomotor model of perception-action coupling, however, is typically framed in terms of intentional actions: whenever I plan to turn on my computer, I can anticipate the sensory consequences of my action plan. While imitation can obviously be intentional (for instance, observational learning is a form of intentional imitation), humans do display very often a type of imitative behavior that is unintentional and pre-reflective, what is typically called “automatic imitation” (Iacoboni 2009).

Top Down and Bottom Up

Observational learning and automatic imitation are perhaps the two imitative behaviors that are situated at the opposite ends of a continuum: the continuum that represents the ever-varying balance between top-down and bottom-up processing of the actions of other people. Observational learning is a top-down intentional imitative behavior that focuses on specific actions and behaviors with very specific goals (how to hit a tennis forehand or how to behave, speak, and even deliberate in specific contexts and situations, for instance). Automatic imitation, in contrast, is clearly a bottom-up process in which the visual input of the actions of others “sweeps us up” so that we cannot help but reproduce that behavior, generally in terms of the postures, facial expressions, and mannerisms of the people we are interacting with. Automatic imitation, however, is not as automatic as its name may suggest. We don’t parrot each other in a zombie-like fashion. Pre-reflective, unintentional imitative behavior is clearly influenced by fairly high-level factors, and in turn, it does influence those factors. For instance, we tend to imitate unintentionally more

people that belong to our social group, compared to out-group members. However, even the influence of social group membership on automatic imitation can be modulated by other contextual factors. Indeed, a competitive situation reduces automatic imitation for in-group members, whereas a cooperative situation increases it for out-group members (Miles et al. 2010). Furthermore, automatic imitation is associated with empathic predisposition. More empathic individuals tend to display more automatic imitation. In experimental settings, being imitated has also been associated with increased liking (Chartrand and Bargh 1999).

Neural Correlates

All these behavioral data suggest that low-level bottom-up processes continuously interact with high-level top-down ones during imitative behavior and that these interactions are modulated by contextual variables and intentional predispositions. Imitation is in itself a complex behavior, and these complex, nuanced contextual modulations make it even more so. What are the neural mechanisms of imitation? Given its complexity, especially in real-world scenarios, for many years, the neuroscience community had largely avoided the study of the neural underpinnings of imitation. A breakthrough discovery in monkey neurophysiology, however, has inspired a recent wave of neuroscience studies on human imitation.

A subset of motor neurons in the monkey brain have surprising visual properties. Even when the monkey does not move at all and is simply watching, these motor neurons fire, as long as the monkey is observing someone else making the same action triggered by the firing of these motor neurons when the monkey moves (or a similar action that achieves the same goal) (Gallese et al. 1996). In other words, the visual properties of these neurons mirror their motor properties, and for this reason, they have been called mirror neurons.

Mirror neurons clearly support more the ideomotor model of perception-action coupling, which assumes shared coding or representations

for perception and action, than the sensory-motor model which assumes independent coding for perception and action. They also seem to have ideal properties to support imitative behavior, especially of the automatic type, since these cells seem to fire in a stimulus-dependent fashion (when the action is seen).

Depth-electrode recordings in both monkeys and humans have provided evidence for mirror cells in a number of neural systems coding for different kinds of actions performed with different body parts (Iacoboni 2011). These findings support the variety of imitative behavior that humans display. However, an outstanding question with regard to the neural underpinning of imitative behavior is also how neural mirroring gets controlled so that the nuanced modulation of imitative behavior due to contextual and dispositional factors can also be accounted for. Early studies pointed to the dorsomedial prefrontal cortex (dmPFC) and the temporoparietal junction (TPJ) as two areas controlling imitation. These areas have been associated with a number of behaviors and cognitive functions, including theorizing about the mental states of other people (theory of mind or ToM). Insofar as imitation control requires a differentiation between the action of the self and the actions of other people and theory of mind requires a differentiation between one's mental state and the mental states of others, the involvement of dmPFC and TPJ in both imitation control and ToM makes sense.

Recent studies have provided more insights on the complex and continuous interplay between bottom-up and top-down neural processes associated with imitative behavior and its control. For instance, a neurophysiological phenomenon analogous to automatic imitation is "motor resonance." When observing someone else making an action, the excitability of our own motor system increases. This increase is "muscle specific," that is, it is restricted to the same muscles used in the action we observe. Motor resonance has been considered for many years a typical automatic, stimulus-dependent process. However, a recent study shows that when planning not to imitate, motor resonance is abolished (Cross and Iacoboni 2014). Note that the plan "not to imitate" is a very

general, high-level plan in this study, because subjects still don't know which action they are supposed not to imitate, which means that fairly high-level intentions ("I am not going to imitate whatever I see") are able to modulate in a top-down fashion a typical bottom-up process like motor resonance.

A brain imaging study on automatic imitation recently attempted a more detailed description of the frontal lobe circuitry for imitation control. Here, dynamic causal modeling (DCM) revealed a circuitry composed of dmPFC and anterior cingulate cortex (ACC) that together trigger top-down inhibitory control – via the anterior insula – of the posterior inferior frontal cortex (pIFC), an area strongly associated with imitation and mirror neurons (Cross et al. 2013). Furthermore, another brain imaging study on controlled imitation, in which subjects were instructed whether to imitate or not, suggested that connectivity changes between brain areas activated by the task was a key regulatory factor for inhibition of imitation (Cross and Iacoboni 2013). Taken together, these findings may explain why the dmPFC is so often implicated in the top-down regulation of imitation. Indeed, dmPFC has a rich connectivity pattern with other neural systems, and this anatomical feature may make it ideally situated for the control of imitative behavior, also in light of the presence of mirror neurons in a number of neural systems. Recent studies using noninvasive neuromodulation have shown that by transiently downregulating dmPFC, it is possible to modulate fairly high-level forms of social conformity (Holbrook et al. 2015), thus suggesting that imitation grounds social conformity processes through bodily synchronization.

Conclusion

The picture that emerges from these recent studies is rich and intricate, yet exciting, due to the fairly rapid progress in knowledge obtained in the last two decades. Progress on our understanding of imitation and mimicry is likely due to the interdisciplinary work of social, cognitive, and neuroscientists.

Imitation of High-Status Others

To follow as a pattern, model, or example (Merriam Webster).

Introduction

“Imitation, is the highest form of flattery.”

What is imitation? Imitation is the innate conative tendency to behave as others behave in the absence of logically sufficient grounds for behaving in that manner, which simply can mean, copying or mimicking the other person. Carried out by animals-primates and humans alike, help one in acting or becoming like the one copied. Often, used by children as a form of mockery, imitation in itself has a complex scientific concept behind it. Mirroring, in its true self, can explain imitation well. The process of copying the person in front of you, consciously or unconsciously, may give us a sense of belonging, a sense of connection. It tries to put both the individuals at the same level.

Neurobiology

Neurobiologically speaking, the theory of mirror neurons comes to play. Describing the process and reason for imitation can easily be explained by this concept. Mirror neurons act when an animal observes an act and then follows it. The basic ideas being visual signals are converted into motor mechanisms. The premotor cortex, the

supplementary motor area, the primary somato-sensory cortex, and the inferior parietal cortex show consistent activity, which favors mirror neurons. These areas are the core areas to be involved in conversion of visual analogues and cognitive processes, thus strengthening this belief (Huber et al. 2007).

Imitation: A Concept

Evolutionary speaking, imitation has been an important skill. It helps in learning of new skills by conversion of visual inputs into fine motor skills. The process, even though be unconscious, can help us learn; thus there is only gain in such situations. Different types and forms of imitation are described-Starting with lower level animals, young ones imitate parents to learn to gather food. They even imitate parents to speak as seen in parrots. Primates, for example, monkeys, can even mimic humans let alone one another, a skill often exploited by circuses. Children grow up learning by, for example, following parents and teachers alike. A baby can be taught new words by making them repeat, establishing that skills needed for daily living as best learnt by copying. People tend to imitate our elders, following rituals and traditions- their seniors in the workplace, and the only conviction needed, that this will make them reach a better place. Also seen by the society as a whole, the youngsters following the latest fashion trends sported by a celebrity, or we as a nation trying to follow the western ways. Baghot stated “society is imitation”, reiterating the belief. Imitation is all around us, be it the aeroplane that flies or the ship that sets sail. Numerous studies have been conducted which establish the importance of imitation, in child-rearing and education. This further justifies the need for good role models as they enhance good behavior. There are three types of mimicry:

1. Automatic imitation which can be defined as a kind of stimulus-response compatibility effect where the action stimulus (either video or image) is paired with a congruent or an incongruent response.

2. Behavioral mimicry which can be defined as the tendency of people to naturally copy others’ movements during social interactions.
3. Facial mimicry which describes the tendency to mimic others’ facial expressions.

The “chameleon effect” can easily explain what happens during a conversation. Given by Chartrand and Bargh 1999, “chameleon effect refers to the tendency to adopt the postures, gestures, and mannerisms of interaction partners.” The best possible explanation is that it is conducted without the idea to copy and not in conscious awareness (Lakin et al. 2003). So, social interactions while linking non-conscious mimicry and rapport building can be enhanced. Studies conducted express the need for further research on how affiliations and non-conscious memory can be linked in greater detail.

Social Status: A Concept

Why is status so important? Or why is it given so much weightage? Why does everyone around us want to be considered as the high and mighty or an influential persona? Us humans constantly find ourselves battling in out among power hungry creatures, so much so that we often find ourselves guilty of the very same charge. If we have a link, a source, and a connection to someone influential or connected, we never refrain to use it. Let alone using, bragging about the same to our friends and families continue for long periods of time. Have you ever wondered, why is it so? Why are we part of this rat race – where in the sole purpose is, who is the most connected, the most influential, and the most powerful. This struggle continues not only for laymen but also those who in fact are the high and mighty themselves. The fundamental remains the same – status. The concept of status can be explained as “the extent to which an individual or group is respected or admired by others.” High status means more admiration in simple terms. If someone presents themselves as having a high status, they feel they would be respected more by the people around them; more people would like to be like them and would in turn copy them.

In turn, this sets of another cycle of imitation, and this may continue up until the very grass root level. Each individual wants to show the world the best version of themselves, the one overshadowing their flaws. What better way than to act like someone else, someone who we admire and consider perfect, is helping them become a better version of themselves in their own eyes. Imitation may or may not raise the respect or admiration in front of others – society per say, but it definitely raises our level in front us; it can help in building a pseudo confidence – that anything is certain now.

“Power is defined as a possibility to influence others.”

In our society, individuals exerting power are perceived to be influential. If they make themselves appear powerful, they become powerful in the eyes of the perceivers, raising their status and standing. Also, making themselves an object of admiration and glorification. Struggle for power and associated high status is not a new idea for us; power play has been evolving through the ages, be it in politics, sports, offices, or even in our relationships. We tend to follow those in power. Feeling powerless automatically makes us feel that we are vulnerable, although it might not be true in reality; our emotions force us to look upon that direction. Concept of high social status and power is also interlinked – a common notion being that high-status individuals are powerful. But this is no sort of guarantee. This favors change in social interactions in two ways. Firstly, one with high-status individuals and secondly, the one with peers but behaving like a high-status individual.

Imitation and High Status: The Connection

The art of copying imitation in its true self can enhance an individual's social standing – reiterates the fact the social status and power play a role which can modify the chances of an individual to imitate. Also, these play a role in cognitive processing and its multiple forms of the perceiver. Studies have been conducted, which had significant results. Studies have drawn various conclusions

when it comes to social gestures and overall body language when dealing with people at the same strata as the individual themselves and those with a higher social status or power entity. Apart from the inherent changes in the overall demeanor of the person, the tendency on what actions and expressions to mimic may even change. High social status and high power definitely have a role to play, and their presence is of much bigger value than perceived directly. Gestures made while interacting and conversing commonly involve shaking hands, nodding, crossing and uncrossing of elbows, waving, even friendly hugs, and kisses. In order to try to come closer to members of the higher social stratas, in a manner to show them we are alike, individuals tend to follow their line of social communication, be it verbal or nonverbal forms of expression. Mostly picking up the motor movements first and then eventually facial expressions, giving them a sense of belonging (Farmer et al. 2016). During the tasks which are based on automatic imitation memory, high and low power-related gestures can cause greater impacts. For example, an individual when approached having clenched fists may open them when faced with a person they admire. This can further even cause changes in facial expressions, denoting a much more dynamic and holistic change in the overall behavior of that said individual. Although, the individual may think of this as the best possible way to approach the social ladder, is it the best possible way? Speaking from an observers' point of view, if two people are standing in front of one another in similar postures, that of a dominating nature, it may appear that they are arguing or even in polite terms disagreeing with one another. The individual mimicking might even make him feel that he is being mocked or made fun of by copying each and every move and rather than building a rapport or acquaintance; it may feel like an attack. What feels like a natural form of interaction if two people conversing maintain a complimentary posture would give an impression of a confrontation, which could finally shorten the already biased conversation or even lead to abandonment of the said individual. Powerful individuals are used to having others bow down and act submissive or in simple terms complimentary to their gestures. Like while shaking hands, we

expect the opposite hand, a complimentary gesture, it feels normal. The imitation behaviour may seem odd or unnatural. Coming to interactions with peers, Lansu et al. 2015 established that among peers, the influential peers tended to be dissuaded in interacting with other popular or influential peers. They further explored nature of self-esteem with the propensity to imitate a powerful peer. Their findings included “Popular young women with low self-esteem were most likely to imitate a popular peer. Unreferred young women with high self-esteem were least likely to imitate a popular peer.” This in turn establishes the same, peer status of influential and powerful alike control our behavior in social interactions. Although this study was conducted in adolescents, results are applicable to older adults as well.

Conclusion

Various studies have been conducted which establish the fact that our conscious and unconscious memory makes us mimic actions and expressions during social interactions. Imitation has been a string suit of the human nature guiding us and making us learn newer skills directly or indirectly. The tendency to mimic those who are at a higher social position than us is tempting and may happen unconsciously. Although, no definitive gain or association has been established between power, status, and imitation, it does seem to have potential advantages. Further, neurobiological aspects need to be explored in greater details to establish causality.

Imitative Aggression

Mitchell Kirwan

Oakland University, Rochester, MI, USA

Synonyms

[Aggressive imitation](#); [Imitative assault](#); [Media violence](#)

Definition

The imitation of aggressive behavior, modeled by another individual.

Introduction

Imitative aggression, or the imitation of aggressive behaviors modeled by another, serves an

important developmental process. Specifically, imitative aggression may function to use others as models for appropriate behaviors in specific environments or circumstances. By imitating others' behaviors in similar situations, individuals are able to learn vicariously through the experiences of those they model, decreasing their chances for experiencing negative outcomes and increasing their chances for experiencing positive outcomes in those situations. Thus, individuals who utilize imitative aggression are able to maximize their fitness in situations which they themselves have not yet experienced.

Imitative aggression research dates back to Bandura's seminal works, assessing the effects of modeling aggression directed toward bobo dolls on children's aggressive behaviors. These experiments suggested that demonstrating aggression to children made them more likely to imitate that behavior and increased the aggressiveness with which they played in the subsequent experimental sessions (Bandura 1965; Bandura et al. 1961, 1963a, b). These experiments also contributed to the development of social learning theory, which states that learning occurs through direct experience and observing others' behavior. However, subsequent research has been unable to assess imitative aggression as rigorously as Bandura, due to ethical concerns (Barrett 2007). Instead, recent research generally uses exposure to media violence in place of a more direct and intense experimental manipulation, to assess these relationships.

Bandura's Studies on Imitative Aggression

Bandura and colleagues' first imitative aggression study randomly assigned children to an aggressive, nonaggressive, or control condition. Children in the aggressive and nonaggressive conditions were individually led into a room and provided with art supplies. After the child was settled in, the experimenter led a model into the room as well and had them sit on the opposite side of the room from the child. The model had some tinker toys and a mallet to play with, as well as an

inflated bobo doll. In the nonaggressive condition, the model quietly played with the tinker toys when the experimenter left the room. However, in the aggressive condition, the model acted aggressively toward the bobo doll by sitting on the doll and punching it, striking it in the head with the mallet, and kicking it around the room. Additionally, the model also stated several distinct, verbally aggressive phrases while aggressing against the bobo doll. Control participants, on the other hand, did not have any interaction with the model at all. Then, the child was led into a new experimental room, filled with a variety of aggressive and nonaggressive toys, including a bobo doll and a mallet, and were given 20 min to play freely, while raters observed their play through a one-way mirror and coded it as imitative and aggressive, nonimitative and aggressive, or nonaggressive. Results of the study showed that individuals in the aggressive condition were more likely than either control or nonaggressive participants to verbally and behaviorally imitate the model's actions. On the other hand, subjects in the nonaggressive condition were substantially more likely than subjects in either of the other groups to simply sit quietly, without playing with any of the toys at all. These results were the first to show that the observation of others' behaviors is sufficient to elicit imitative behaviors which an individual almost certainly would not have exhibited otherwise (Bandura et al. 1961).

Subsequent experiments by Bandura replicated his original finding and extended the implications to other similar situations as well. For example, in one experiment, aggressive behavior toward a bobo doll was either demonstrated by a real-life aggressive model, in a paradigm identical to Bandura and colleagues' original study (1961), with a film clip depicting a human model behaving in the same manner as the real-life model, using a cartoon film clip, in which a cartoon character behaves in a similar manner to the model in the above conditions or was not demonstrated at all. When children were allowed to play freely, participants who viewed the non-cartoon film clip displayed the most total and imitative aggression, followed by individuals in the real-

life, cartoon film, and control conditions, respectively (Bandura et al. 1963a). Additionally, in a separate experiment, subjects were shown a film clip in which an aggressive child either gets punished for his aggressive behavior or gets rewarded for his aggressive behavior, and only children who observed the child get rewarded for his actions displayed increased imitative aggression during a subsequent play session; those who saw the child get punished showed similar levels of imitative and total aggression to control participants, who did not view a film clip (Bandura et al. 1963b). Finally, one last experiment showed that the inhibitory effects of viewing an aggressor be punished can be eliminated if the researcher subsequently offers the subject a reward for imitating his behavior. Specifically, Bandura (1965) noted that participants who viewed a model get rewarded for his aggressive behavior showed identical levels of imitative aggression as those who saw no consequences of his aggression, but those who saw him get punished were less likely to imitate his behavior. However, after the children in all conditions were offered rewards for imitating the model's behavior, children who previously saw the model get punished showed identical levels of imitative aggression to those in the other two experimental conditions (Bandura 1965).

Social Learning Theory

When trying to determine possible boundary conditions for imitative aggression, informed by social learning theory, Bandura (1986) concluded that the following four elements must be present in order for imitative aggression to occur: First, the individual must pay attention to whomever is modeling their behavior. Without paying attention, subsequent steps of this process would be impossible, as the subject would have no knowledge of the behaviors they were going to imitate. Next, the individual must retain a memory of the aggressive behavior the model engaged in. In order to ensure that the subject retained a memory of the aggressive actions in his experiments, Bandura et al. (1961, 1963a, b) included both

physically and verbally aggressive behaviors, as it would be virtually impossible for a subject to reproduce both types of behaviors spontaneously. Additionally, the model must be capable of imitating the actions of the model, because if they are unable to properly imitate the model's actions for any reason, they will not be able to aggress in the same way that the model did. Finally, the individual must have the desire to imitate the aggression, and such desire is much more likely to be present if he saw the model rewarded for his aggressive actions than if he seems him punished for the same actions or if the subject is offered a reward for imitating the subjects actions (Bandura 1965, 1986; Bandura et al. 1963b).

Ethical Concerns

Due to ethical concerns, recent research has not used procedures similar to Bandura et al. (1961) when assessing imitative aggression. Specifically, the Belmont Report states that one of the fundamental ethical principles for conducting research using human subjects is beneficence, meaning that one must "do no harm" to human participants (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research and Ryan 1978). Since experimentally inducing subjects, especially children, to behave in an aggressive manner is considered harmful (Barrett 2007), contemporary research on imitative aggression does not use procedures similar to those used by Bandura (1961). Instead, researchers have used proxies which they may use in place of directly exposing participants to aggressive behavior, with the intention of having them imitate it.

Contemporary Research and Media Violence

The proxy most commonly used by contemporary researchers of imitative aggression is violence encountered by participants willingly, through their consumption of media, including movies, television shows, and video games. While a

limited amount of research has found little to no effect of violent media and real-world aggression (e.g., Decamp and Ferguson 2016), the overwhelming majority of experimental research disputes this and suggests instead that increased exposure to violent media causes increased levels of hostile expectations (Hasan et al. 2013), increased aggressive cognitions and affect (Carnagey and Anderson 2004) short- and long-term increases in aggressive behavior (Huesmann, Moise-Titus, Podolski, & Eron, 2003), and an overall negative impact on the effected population (see Huesmann and Taylor 2006 and Wiedeman et al. 2015 for reviews). Thus, although the study design associated with research assessing aggressive or violent media cannot assess the imitative nature of the increased aggression as stringently as Bandura's studies did, the tenets of social learning theory suggest that much of the increases in aggression caused by exposure to violent media may be due to increases in imitative aggression by those who are exposed to it.

Sex Differences

Since Bandura's initial studies, researchers have also been interested in how imitative aggression may affect male and female participants differently. Early work examining possible sex differences in imitative aggression largely showed that males tended to be more aggressive than females were. However, more recent research has not consistently replicated this finding. Specifically, Bandura's seminal bobo doll studies showed that, in most cases, male participants displayed higher levels of both imitative and nonimitative aggression than females did (Bandura 1965; Bandura et al. 1961, 1963a, b). However, more recent research examining sex differences and the effects of exposure to media violence have been mixed. For instance, a study by Bartholow and Anderson (2002) showed that playing a violent video game caused an increase in aggression relative to a nonviolent game in both sexes but that this effect was larger in male participants than it was in female participants. On the other hand, other studies have found that there are no sex

differences when examining the effect of exposure to violent video games (Hasan et al. 2013) or other violent media (Bushman 1995), on subsequent aggressive behaviors.

Conclusion

Bandura's groundbreaking studies demonstrated that viewing specific, aggressive behaviors causes children to imitate those exact behaviors, especially when they are associated with receiving a reward or even a lack of punishment (Bandura 1965; Bandura et al. 1961, 1963a, b). Although contemporary research does not induce specific aggressive actions for ethical reasons (Barrett 2007), research on the effect of media aggression demonstrates that exposure to violent media causes increases in aggressive cognitions, affect, and behaviors (Carnagey and Anderson 2004; Hasan et al. 2013; Huesmann et al. 2003), which may be due, in part, to increases in imitative aggression. Future research on imitative aggression should more closely examine this relationship, to determine the extent to which the increases in aggression are due to direct imitation, rather than more general increases in aggression. Additionally, research should seek to more definitively determine whether men are more susceptible to the effects of media violence than women are or if this is merely an artifact of cultural influences.

Definition

Immigrant A person who goes to live permanently in a foreign country.

Bilingualism The practice of speaking or signing in two or more languages, with varying degrees of proficiency. Synonym, multilingualism.

Majority, or Societal Language A language spoken by the majority of the inhabitants of a given region.

Minority, or Heritage Language A language which is not the language of the community, spoken by indigenous peoples or immigrants as part of their cultural heritage, includes the whole

range of mastery, from only a few words and incomplete grammar to full fluency.

Introduction

All humans, except victims of heinous child neglect, grow up speaking the language of their caregivers (Pinker 1994; Rhymer 1993). Indeed, given the right circumstances and enough support for it, people become fluent in two or more languages, such that more than half of the world's population is estimated to be multilingual (Crystal 2004). When children are raised in a language from birth, they become members of their caregivers' language community. Children who master a second language before puberty (Hyltenstam and Abrahamsson 2000; Lenneberg et al. 1967) are most likely to learn it without an accent that would mark them as outsiders and can enjoy membership as "insiders" in a second language community. Beyond the instrumental value of enabling direct communication with a larger number of people and access to more economic and cultural resources, participating in an additional language community gives a powerful sense of belonging and strengthens emotional ties with speakers of that language (Gardner and Lambert 1972).

Patterns of Language Use and Abilities Among Immigrant Children

Immigrant parents migrating together to a country where a different language is spoken generally expect that their children will become bilingual in their language of origin, or "heritage language," and the language of their new host country. The parents might attain some fluency or even deep knowledge of the language of their adopted country, but unlike their children, their speech will likely mark them as foreigners there throughout their lives. Although children may start out slowly, even to the point of having a silent period of several months (Tabors 2008), more typically, they learn a new language to "playground standards" (Basic Interpersonal Communication

Skills) within the first year, sometimes within a few months (Cummins 1979a). Even children as young as 6 years have been observed to take on the role of language broker for their slower-learning parents. It takes the child longer to develop enough proficiency for age-appropriate progress in academic programs in the medium of the new language, acquiring Cummins' "Cognitive Academic Language Proficiency," or CALP, within 3–5 years. Finally, proficiency levels asymptote about 8 years post-immigration (Hakuta and D'Andrea 1992). Most developed countries have school programs to transition immigrant children to the societal language, and children need little encouragement to adopt the language and the popular culture of their new peers.

Less certain is the fate of the language of origin. Immigrant parents are often so focused on their children learning the new language, they take the first language (L1) for granted (Jarmel and Schneider 2009). While learning a second language (L2) does not require the loss of the first, without special attention to the first language in the process of learning the second, a weakening or loss of the language of the homeland is more likely than proficient bilingual abilities (Lambert 1977). Thus, in theory, children of immigrants are in an ideal position to establish robust bilingualism that will allow them to participate as full-fledged members of two language communities. In practice, however, that is not always the case.

Language Assimilation Across Generations

The classic timetable for linguistic assimilation into a new language community spanned three generations (Dorian 1982; Haugen 1972): the immigrants themselves remained stronger, or "dominant," in the old language; their children, the second generation, learned or retained the old language but became native or near-native speakers of the new language; and the grandchildren were dominant, or even monolingual in the new language. However, linguistic assimilation in the USA appears to have been

compressed into two generations (Rumbaut et al. 2006; Veltman 2000), or less (Polinsky and Kagan 2007).

“Generation,” in any event, may be too coarse a term to adequately describe the language outcomes for the many different trajectories of immigrants. Hakuta and D’Andrea (1992), in a study of several hundred Mexican-background teenagers in California, subdivided the generations in order to probe more carefully which children would become robustly bilingual, and who would struggle with one or the other language. In their analysis, three generations became six “depths.” Depth 1 comprised those who immigrated after age 10, (with an average of 3 years in the USA at the time of the study); Depth 2 arrived in the new country between ages 5 and 10; and Depth 3 arrived before age 5. The second generation was split according to whether both parents were born abroad (Depth 4) or only one (Depth 5). Depth 6 comprised the third generation, that is, students with at least one parent and associated grandparents born in the USA.

Proficiency measures showed that children at Depth 3 (from the first generation) and Depth 4 (from the second generation) had the strongest skills in both languages. The English of Depth-2 children showed significant progress over Depth 1, but both groups remained dominant in their L1. At the other end of the spectrum, proficiency levels for Depths 5 and 6 were not significantly different from each other. Both showed weak Spanish scores and strong English scores. Importantly, the high level of skill in **both** languages of Depths 3 and 4 demonstrated that progress in English did not depend on loss of Spanish. Interviews revealed that the choice to speak predominantly in the majority L2 shifted before proficiency did. Parent language preferences shifted later, after Depth 4.

Patterns of Bilingual Language Use in the Home

In contrast to children with two parents who spoke the same heritage language in the home, children with parents who immigrated separately from

different countries, or with only one immigrant parent, have different language resources. A common household arrangement for this group, especially popular in Europe and Canada, is for one parent to speak one language to the child and the other to speak another language – so-called OPOL, “one parent/one language.” One of these languages may be the community language, but often the community language will be a third language. De Houwer (2009) investigated family language practices and bilingual outcomes for 1,450 mostly Dutch/French families in Flanders, and she reanalyzed Yamamoto’s (2002) report of 188 bilingual families in Japan. The analysis took into account whether the family used OPOL or another strategy and whether the mother was the source of the minority language. Like Hakuta, de Houwer found that the crucial element was for both parents to speak in the minority language in the home. Fewer than half of the children with parents who spoke together in the societal language grew up speaking two languages, whereas when the parents spoke together in the nonsocietal language, more than 93% of their children spoke both that language and the societal language.

Conclusion: Language Transmission in Bilingual Communities

According to Haugen (1972) and Fishman (1991, 2001), community bilingualism is transitional. When two languages compete in the same domains, one language will win out. Fishman’s advice to maintain or revive bilingualism is for the weaker language to carve out a location or function – e.g., the home or religious observances – where the minority language is used exclusively and language choice does not need to be constantly renegotiated.

Fishman’s cautions are most commonly understood in the context of indigenous languages at risk for extinction, not with a language that ranks high on the UN Language Vitality Scale like Spanish in Miami-Dade County, Florida (UNESCO 2003). Hispanic immigrants are more numerous than native born, and government,

business, and educational leadership are in the hands of the immigrants who control most of the wealth of the region (US Census 2015). Four-fifths share a global language, with millions of speakers in many localities around the world (Moseley 2010). There should be ample support for the “majority-minority” language to be transmitted to succeeding generations. However, researchers have found in Miami that “Depth 4”/second generation children speak mostly “kitchen Spanish” if they speak Spanish at all, and even fewer are literate in their L2 (DCPS 2015; Hassan 2006; Oller and Eilers 2002).

Why would so few children in the second generation there learn or speak the language of their immigrant parents? Two causal factors stand out. (1) Lack of awareness. With continued immigration fueling the overwhelming presence of Spanish on the street and in media in Miami, there is no sense of threat to the language (Glazer 1966; Eilers et al. 2002). Possibly, parents would be more motivated to take specific steps to transmit the language to their children if, instead of full acceptance, there were harsh suppressions against it, like those for example, imposed unsuccessfully on Catalan in Franco’s Spain. (2) Lack of education in Spanish. In Miami, children of immigrants enter a primarily English-only educational system. In most states, including Florida, there is no law precluding education in two languages, and there is a strong research base to support it (Collier and Thomas 2004; Cummins 1979b; Oller and Eilers 2002), but ironically, it is rarely offered. Only a handful of schools offer a dual-language curriculum (CAL 2004; DCPS 2015).

In a running survey over the course of 10 years, several hundred Hispanic-heritage students in Miami from middle school through university, (Eilers et al. 2006; Pearson and McGee 1993) almost all said they wanted their children to learn Spanish. However, on the very same survey, the students gave evidence against their being able to do so. They reported that they, themselves, spoke to their parents at least half in Spanish when the parents spoke to them in “mostly Spanish,” especially if both their parents were recently arrived in the United States. However, when the students were free to choose their language,

with siblings and friends for example, most reported speaking “mostly English with a few words of Spanish,” a pattern observed within the first generation, within their first months in this country (Pearson and McGee 1993). Unless these students, when they become parents, were to make a more intentional effort than their parents did to maintain their heritage language in the home and advocate for heritage language programs in their schools, they would be unlikely to reverse the natural shift toward the majority language.

Immune Response to Disgust and Disease Cues

Diana Fleischman

University of Portsmouth, Portsmouth, UK

Synonyms

Disease cues and immune response; Disgust and immunity

Definition

The degree to which the immune system responds to disease cues.

Introduction

Pathogens including viruses, protozoa, bacteria, and parasites, including helminths (worms), ticks, and mites, have been an important selective force for all multicellular organisms. Pathogens and

parasites take energy and resources from their hosts. They use their hosts to reproduce and make copies of themselves siphoning off calories and interfering with physiological processes. There is evidence that some pathogens and parasites alter hosts' behavior and physiology to their own adaptive ends (e.g., some parasites sterilize their hosts). Two systems have evolved to prevent, mitigate, and eliminate infection. The immune system, a set of specialized cells and mechanisms, is mostly engaged when parasites and pathogens have entered the organism. The immune system fights infection by, for example, producing enzymes to destroy the structure of the parasite or creating antibodies that can neutralize pathogens. The other adaptive system, sometimes called behavioral prophylaxis or the behavioral immune system (BIS), is a suite of evolved strategies to minimize the risk or prevent the introduction of pathogens and parasites into the organism. Examples in animals include selectively grazing away from feces or avoiding sick conspecifics. The human BIS is thought to center around the emotion of disgust. Recently, researchers have discovered that the BIS and the immune system are responsive to one another. For example, there is some evidence that immune vulnerability makes people more sensitive to disease cues (Miller) and that disease cues (e.g., seeing a sick looking person) can activate the immune system.

This entry will focus on human literature showing immune response to disgust and disease cues. The functional rationale behind this work is that perceiving disease cues is indicative of likely imminent infection and the most adaptive response is an anticipatory mobilization of the immune system.

Measure of Immune Activation: Cytokines, Antibodies, Proteins, and Body Temperature

Immune response in psychological studies is measured both in blood and in saliva. Blood is often considered a better and more direct method. However, salivary markers are easier to collect. Because the mouth is one of the main entryways

for pathogens, we might expect immune defenses to be mobilized preferentially in the mouth (Stevenson et al. 2011). A few kinds of immune marker are measured in these studies. Cytokines are proteins that act as messengers for the rest of the immune system and can activate other cells (Delves et al. 2011, p. 6). In particular, these kinds of studies are interested in inflammatory cytokines, messengers that recruit cells to sites of infection. However, it's important to remember that cytokines do not have a unitary function and many cytokines have both anti-inflammatory and pro-inflammatory properties. Immunoglobulins are antibody molecules that usually bind to pathogens neutralizing them or tagging them as "foreign" for other cells to clean up (Delves et al. 2011, p. 36). Immunoglobulins have classes based on their variable molecular structure. Most of these studies focus on what are commonly termed "innate immune" markers; these aspects of immunity are the first line of defense against pathogens because they distinguish the body's own cells from foreign and infected cells without previous exposure to the pathogen.

One study (Stevenson et al. 2012) also looked at body temperature. Body temperature may be increased to (1) make the body less hospitable to pathogens that are adapted to live in a certain temperature range and (2) increase metabolism and thus hasten the production of antibodies and other immune components (Kluger et al. 1996).

Thermal and Immune Response to Disease Cues

Five studies have investigated how exposure to disease cues or disgust activates aspects of the immune system. Schaller et al. (2010) conducted the first study, randomly assigning 28 participants (both men and women) to either watch a neutral slideshow and then a gun slideshow (fear condition) or a neutral slideshow and then a disease slideshow (disgust/disease condition). Participants came in on separate days and had blood drawn before and after the neutral slideshow and the experimental slideshow. The blood samples were incubated with a compound that the immune

system perceives as a bacterial infection and then were measured for inflammatory cytokine interleukin-6 (IL-6). Participants in the disease condition showed greater increase in blood IL-6 response (23.6%) than participants in the fear condition (6.6%).

Stevenson et al. (2011) examined salivary immune response to disgust. Stevenson et al. (2011) randomly assigned 92 male participants under 30 years of age to a disgust condition, a negative affect control condition or a neutral control condition. They measured antibody salivary immunoglobulin A (IgA) and inflammatory cytokine TNF-alpha (TNF- α).

They found a decrease in IgA and an increase in TNF- α in the disgust relative to control conditions. Disgust stimulates increased salivation, possibly to protect the tooth enamel from intestinal acids. The authors surmise that this is why there was a decrease in the concentration of IgA.

Stevenson et al. (2012) conducted another study on 74 male participants randomly assigned to look at disgusting food, pleasant food, nonfood-related disgusting images, and a negative affect control. Again they measured IgA and TNF- α , but they also measured core body temperature (BT). IgA showed a different pattern for disgusting food than for nonfood-related disgusting images. The disgusting food condition showed a sharp increase in IgA posttest and a subsequent decrease. The nonfood-related disgust condition showed a decrease in IgA like the previous study. TNF- α increased across both disgust groups (food and nonfood) relative to both control groups (food and negative). This was the first study to demonstrate a significant increase in body temperature from disgust induction; participants in the disgust conditions were 0.3 °C warmer than the participants in the control conditions.

Ersche et al. (2014) looked at salivary immunological reactions in men, 31 cocaine addicts and 30 controls. Like the previous Stevenson et al. study, they compared food and nonfood images in both the disgust and neutral categories.

They measured salivary cytokines IL-6, IL-1beta (IL-1 β), TNF- α , interferon-gamma (IFN- γ), and IL-12, IL-10, and IL-8. All group

comparisons controlled for an inflammatory marker known as C-reactive protein (CRP) which was significantly greater in cocaine addicts. They found IFN- γ , IL-1 β , IL-6, and TNF- α were significantly increased after viewing disgust stimuli in all men.

Stevenson et al. (2015) noted that previous studies haven't found a relationship between self-reported disgust and immune activation. They designed a study that uncoupled disgust and disease stimuli creating three sets of images: (1) disgusting but minimally disease related (e.g., a dead cat), (2) disease related but minimally disgusting (e.g., a woman sneezing), and (3) a negative control. Thirty-nine male participants viewed all sets of images 1 week apart. In this study, none of the conditions caused an increase in salivary TNF- α or IgA. The researchers found that TNF- α increased in the subset of participants with high trait disgust for both the disgust (1) and disease (2) image sets.

Conclusion

The examination of how disease- and disgust-related emotions and cognitions influence immunity is still in early stages; these studies have been conducted on mostly male participants with mostly salivary markers. Thus far it seems that many inflammatory cytokines, some antibodies, and body temperature are influenced by exposure to disgusting and disease-related cues.

Introduction

The immune system is an essential biological system which ensures the survival of the organism by providing protection against offending agents (pathogens – including bacteria, viruses, fungi, parasites, etc.). Intactness of immune system is required for the survival of the individual. Optimal functioning of the immune system is essential for a healthy body. Either a compromised or overactive immune system can be associated with health hazards. A compromised immune system increases the vulnerability to acquire infections, whereas an overactive immune system has damaging effects on body's own tissue (van der Most et al. 2011). Immune system and good health have a bidirectional relationship, one promoting the other (Murray 2013). Many factors related to day-to-day life (e.g., life style, exercise, diet, stress, substance use) influence the immune system (Murray 2013).

Structure and Functioning of the Immune System

The immune system comprises a group of cells and organs distributed in the body which together provide protection against pathogens entering through, or multiplying in, any part of the body (Delves and Roitt 2000; Janeway et al. 2005). It is composed of primary (bone marrow and thymus) and secondary (lymph nodes, spleen, and mucosa-associated lymphoid tissues {MALT}) lymphoid organs. The primary lymphoid organs are responsible principally for the production of immune cells and their education. The developing immune cells undergo a process of positive selection and negative selection in these primary lymphoid organs. In positive selection the cells recognizing their MHC molecules survive. In negative selection lymphocytes that recognize self-antigens are eliminated by inducing apoptosis or anergy (state of unresponsiveness to antigenic stimulus). The secondary lymphoid organs have designated zones for T cells and B cells within them. The naïve T and B lymphocytes get exposed to the

Definition

The benefits an individual receives due to its own immune system.

antigen in these organs, following which they mature and proliferate.

The immune system is divided broadly into innate (natural) and adaptive (acquired) arms (Delves and Roitt 2000). The first line of defense against any microorganism is an intact skin and mucous membranes. *Innate immune system:* This arm of the immune system is not directed against any specific pathogen but instead provides protection against all infection in general. It is present since birth by virtue of an individuals' genetic or constitutional makeup. The components are pre-formed and fully active; thus, they can function immediately upon entry of the microorganisms. The innate immune system includes various cells like – neutrophils, basophils, eosinophils, mast cells, macrophages, and natural killer cells. These cells can kill the pathogen either by phagocytosis and subsequent intracellular killing (neutrophils, macrophages) or by releasing certain chemical mediators (eosinophil, basophil) (Delves and Roitt 2000).

Adaptive immune system: This arm of immune system recognizes and mounts an action against specific components of the pathogen called an antigen. Activation of the acquired immune system requires prior exposure to the offending antigen. It takes several days before becoming fully effective. This arm of the immune system improves with repeated exposure to the antigen by the virtue of its memory component. Adaptive immune system acts by the proliferation of lymphocytes (T and B cells) that possess receptors which can specifically identify and attach with the antigen. Levels of antigen, strength of binding between antigen and its receptor located on the surface of lymphoid cells, as well as period of antigenic exposure determine the immune response (Zinkernagel and Hengartner 2001). Adaptive immune system has two arms, namely, humoral immunity and cellular immunity. B lymphocytes, plasma cells, and antibodies produced by them contribute to humoral immunity. T lymphocytes (classified mainly into helper T cells, cytotoxic T cells, and regulatory T cells) contribute to cell-mediated immunity.

Antigen-presenting cells (APCs) and complement system connect the innate arm with the

adaptive arm of the immune system (Rus et al. 2005; Yatim and Lakkis 2015). Antigen-presenting cells (macrophages and dendritic cells) capture large structures and break them into smaller fragments, mostly peptides. APCs process the antigenic peptides, pack them into major histocompatibility complex (MHC) proteins and present them to T lymphocytes possessing the appropriate T cell receptors. APCs also provide additional costimulatory signals, causing activation of the specific subset of T lymphocytes. This leads to clonal proliferation and differentiation of those T lymphocytes. Subsequently, antigen-specific B lymphocytes become activated (by the APCs and helper T cells) and produce antibodies. There is exponential increase in the number of antigen-specific clones of both T and B lymphocytes in response to any antigen. This is followed by the death of most of these lymphocytes; however, a few of them survive to become the long-lived memory cells. Memory cells ensure rapid and more effective immune response on a subsequent encounter with the same pathogen. Several chemical mediators' including chemokines and adhesion molecules are also involved in signal transfer and appropriate coordinated function of the immune system (Yatim and Lakkis 2015). The complement proteins belong to the innate arm of the immune system. Activation of the complement system can occur via three pathways (classical, alternate, and lectin binding pathways). The classical pathway activation requires antigen-antibody complex formation and thus involves the adaptive immune system. Alternative pathway activation and the lectin pathway are considered as a component of innate immunity because they are activated by various components of the pathogens and do not need antigen-antibody complex formation for activation.

Benefits of Immune System: Evidences

The immune system can be modulated by stress, and it helps in combating stress. The health hazards of stress result from failure of the immune system (activation of the hypothalamo-pituitary-

adrenal axis resulting in hypercortisolemia and increased catecholamines leading to down-regulation of the immune system) (Murray 2013). Life style interventions, stress management, relaxation techniques, and positive mood states are known to boost the immune system and thereby attenuate the stress response (Murray 2013). Optimal functioning of the immune system is responsible for producing a state of subjective well-being. Good sleep is also associated with optimal immune function and vice versa (Murray 2013). Evidence also supports the hypothesis that sex hormones (estrogen, testosterone) have an immunomodulatory effect (Foo et al. 2017). Hence, an optimally functioning immune system is likely to boost sexual function.

The mucosal surfaces of the body (e.g., mucous membranes of the gastrointestinal tract, respiratory tract, urogenital tract) are exposed to varied pathogenic bacteria and antigens daily. Mucosal immunity, which is mainly provided by immunoglobulin A produced locally (secretory IgA) and secreted into mucus, is largely responsible for dealing with these antigens. For example, a variety of foreign antigens enter the gut via food. The local immune system of the gut has evolved sufficiently to balance immune response to ingested pathogens, gut microbiome, and ingested antigens. The gut-associated lymphoid tissue (GALT) is able to detect and subsequently kill pathogens entering the gut. At the same time, it prevents vigorous immune response against food antigens by a phenomenon called oral tolerance. *“Oral tolerance is classically defined as the suppression of immune responses to antigens (Ag) that have been administered previously by the oral route”* (Faria and Weiner 2006). Oral tolerance has therapeutic implications in prevention of autoimmune disorders, hypersensitivity reactions, and other conditions where the immune system is dysregulated (Faria and Weiner 2006; Wawrzyniak et al. 2017). Inability of GALT in balancing these functions adequately may lead to autoimmune disease. Autoimmune diseases (e.g., autoimmune anemias, Graves’ disease, systemic lupus erythematosus, rheumatoid arthritis, scleroderma, multiple sclerosis, etc.) are caused due to self-reacting T cells or autoantibodies.

Inflammatory bowel diseases (IBD), for example, are caused due to an immunological imbalance of the intestinal mucosa. T lymphocytes acting against self-antigens lead to a chronic inflammatory condition in IBD patients (Davies and Abreu 2015). Oral tolerance therapy has been examined as a strategy for preventing and treating these conditions.

Gut microbiome also contributes to the human immune system. The gut microbiome has a symbiotic relationship with the host (human). Gut microbiome produces local immunity (by encountering the pathogens that comes in contact with gastrointestinal tract) as well as helps in development of the brain and regulation of behavior (Heijtz et al. 2011; Round and Mazmanian 2009). Any alterations to the gut microbiome are likely to alter the immune system. Hygiene hypothesis proposed that the increased incidence of atopic diseases including asthma is due to a lower incidence of infection in childhood due to vaccination, increased antibiotic use, and reduced exposure to helminths. Though there is debate surrounding this concept, there is no denying that for a healthy immune system to develop, parasitic helminths and commensal microbial organisms are vital (Bloomfield et al. 2016; Stiemsma et al. 2015). Evidences suggest manipulation of the intestinal microbiome may help to treat and even prevent immune dysregulation in the form of atopic diseases.

Immunodeficiency disease results when the immune system of the body is impaired. Primary immunodeficiency diseases result from inherited defects in any component of the immune system. Secondary immunodeficiency diseases occur as a consequence of immunosuppressive conditions like HIV/AIDS, chemotherapy, autoimmunity, etc. Immunodeficiency conditions (DiGeorge syndrome, Wiskott-Aldrich syndrome, Chediak-Higashi syndrome, etc.) increase the susceptibility of the individual to infections and even certain cancers.

Breast milk contains secretory IgA, and thus, breast-feeding in neonates and infants helps in immune development. The immune system in return protects the infant from infections, allergy, and autoimmune disorders (Jackson and Nazar

2006). Evidence suggests that critically ill patients (following sepsis, postsurgical, and post-trauma patients) receiving immune-enhancing enteral nutrition had lesser infection rate. These patients also spent fewer days in ventilator and had shorter hospital stays (Beale et al. 1999). This indicates that immunomodulation has beneficial effects on general health by facilitating recovery from critical illnesses. The immune system also has an important role in cancer pathogenesis. The pathogenesis of cancer is mediated through disruption of immune regulation, and the immune therapy for cancer treatment restores this breach in the immune system (Andersen 2015). Hence, the immune system has a substantial role in preventing cancer.

The immune system interacts with the neurocircuitry and neurotransmitter system involved in regulation of behavior. The immune system also regulates stress response, neuronal growth, as well as degeneration (Miller et al. 2017). Hence, an optimal functioning of the immune system is highly essential for mental well-being. Recent evidence suggests that aberrations in the immune system (particularly in the cytokine profiles) are associated with development of neurodevelopmental disorders like – autism spectrum disorders (ASDs) (Masi et al. 2017).

An exaggerated response of the immune system during inflammation results in tissue damage. Neuroinflammation results in neurodegeneration, abnormal neurotransmission, and aberrant neuro-conduction. This has been implicated in the development of neuropsychiatric disorders like schizophrenia and mood disorders (Thibaut 2017). Restoring the integrity of immune system may be beneficial in recovering from mental illnesses.

Mind-body therapies (yoga, meditation, tai chi, and qi gong) have immune-boosting effects. These psychological therapeutic techniques produce a relaxation response via reduction of anxiety and stress. Evidence supports the hypothesis that these therapeutic techniques used over 7 to 16 weeks reduce the level of inflammatory markers (c-reactive protein, interleukin –6) and to some extent improves antiviral-related immune response (Morgan et al. 2014).

Conclusion

The immune system plays a pivotal role in protecting the humans from pathogens and harmful agents. An intact and well-functioning immune system is essential for good health and longevity. Across the lifespan of an individual, the efficiency of immune system changes. Similarly, with time, the immune system in the organism evolves to meet the needs of encountering differently evolving pathogens (e.g., mutated microorganisms, new environmental toxins). To receive the continuous benefits from the immune system, appropriate measures (e.g., good diet, better life style measures, appropriate preventive measures) need to be taken so as to maintain the integrity of immune system.

Impact of Early Theory on Charles Darwin

Vicki K. Bentley-Condit¹ and E. O. Smith²

¹Department of Anthropology, Grinnell College, Grinnell, IA, USA

²Department of Anthropology, Emory University, Atlanta, GA, USA

Introduction

Charles Darwin was the one of the greatest minds of the nineteenth century, with remarkable synthetic abilities and powers of observation. However, ideas about evolution had been around for some time. In fact, aspects extend back to the ancient Greeks and Romans. While not every historical development can be incorporated into this essay, taking a historical perspective on the development of evolutionary theory allows one to appreciate more fully the extraordinary clarity and understanding possessed by Darwin.

Pre-Renaissance

Twenty centuries before Darwin, the Greeks were developing an understanding of the origin and development of life. Thales (c. 636–546 BC) presented a mechanistic explanation for the world. He emphasized a physical basis for all things, proposed water as the basic building block of all living and nonliving matter, and was one of the earliest precursors of modern scientific thought. Empedocles (c. 495–435 BC) was responsible for the four classical elements approach to understanding the world – water, air, earth, and fire – but also discussed the evolution and origin of organisms. He believed the parts/organs of organisms formed first and would then come together by chance to form different organisms. Those organisms with good combinations survived; those with bad combinations did not. These mechanistic understandings of how things worked gave way to the Greek Classical Period as illustrated by Aristotle (Bardell 1994; Kirk et al. 1983).

Aristotle (384–322 BC), a student of Plato, was the foremost biologist of his time. His ideas about physiology were so sophisticated that they were not demonstrated to be incorrect until the seventeenth century, while his descriptions of marine species endured until the eighteenth and nineteenth centuries. His notions about embryonic development were elaborated into a theory of epigenesis in which the early stages of a being do not resemble the adult form, radical for the time since it was generally accepted that embryos were scaled-down versions of adults. Aristotle originated the concept of genus and species. Of particular importance for things to come was Aristotle's arrangement of organisms in a static hierarchy according to their complexity. Aristotle discussed the work of Empedocles; Darwin commented upon both Aristotle and Empedocles in the *Origin* (Bardell 1994; Kirk et al. 1983).

Approximately 200 years later, Lucretius (c. 99–55 BC), a Roman philosopher, described the development of the world and all things in it through natural processes, i.e., without any supernatural involvement. While these ideas were not necessarily mainstream, they influenced the approaches of some of the philosophers who

followed. For example, Augustine of Hippo, a fourth-century theologian, argued that the creation story in the Book of Genesis should not be taken literally. Rather, he stated that forms of life had changed slowly over time. Thomas Aquinas (1225–1274) built upon and refined the ideas of both Aristotle and Augustine and “perfected” the Great Chain of Being which went on to influence scientific thinking for centuries to come. However, even Aquinas recognized that nature was a force that worked upon the natural world and its inhabitants – albeit following supernatural guidelines. Darwin's ideas regarding causation can be traced back to Augustine. Darwin also discussed Aquinas' work 600 years later with his colleague Asa Gray (Kirk et al. 1983; Lovejoy 1936; Maurer 2004; Phipps 1983).

Renaissance

The sixteenth and seventeenth centuries saw an explosion in the naming and identification of plants and animals. The greatest classifier of both plants and animals of the period was an Englishman, John Ray (1627–1705), who combined his interests in natural history and theology. Ray made the first distinction between monocotyledonous (having one embryonic leaf in the seed) and dicotyledonous (having two embryonic leaves in the seed) plants. He also identified a group of animals including bats and whales that possessed hair, breathed with lungs, had a heart with two ventricles, and gave birth to live young. These animals would eventually be called mammals, but Ray was the first to identify them as a group based on similar anatomical characteristics. His masterwork, the three-volume *Historia Plantarum* (1686–1704), anticipated the work of future scientists by recognizing the fundamental validity of the species concept and the possibility of variation within breeds, even though he viewed species as unchanging. Ray also made an attempt to synthesize science and religion that had a far-reaching impact. He argued that the order in design of things in nature demonstrated the existence of a benevolent and omnipotent creator, and he suggested most of the familiar examples of

purposive adaptation that some still use today to question the validity of evolution by natural selection. These include the structure of the eye, the hollowness of bones, the stomach of a camel, and the armor of the hedgehog (Eiseley 1958).

Post-Renaissance

Explorations of new and uncharted lands during the Renaissance contributed to a heightened interest in nature among both scientists and philosophers and a decrease in reliance upon the classical writings of antiquity. Georges-Louis LeClerc, Comte de Buffon (1707–1788), a central figure in the intellectual history of eighteenth-century science in Europe and a contemporary of Linnæus, exemplifies this interest in nature. Buffon is best known for his 44-volume work, *Histoire Naturelle* (1749), which dealt with everything then known about natural history. At the time, Buffon was more widely read than Linnæus (Eiseley 1958; Roger and Williams 1997).

Buffon's influence on the development of the theory of evolution is often underestimated. He contributed four major ideas that addressed central themes evolutionists would later address. First, Buffon recognized that there was some type of relationship between apes and humans. This is important because religious opinion at that time denied any relationship and emphasized *man's* domination over the earth. Second, Buffon recognized not only the biological reality of the species concept but also how it is applied in nature. Simply put, he stated that organisms that are not of the same species cannot interbreed. Third, he described the formation of the Earth by existing processes, not by supernatural intervention. Buffon was one of the first to suggest that the world was considerably older than many believed. Finally, Buffon discussed the altriciality (helplessness) of humans as compared to other species, conducted the first longitudinal human growth study, and thought that heat exerted a considerable influence on the growth of the body, thus supporting the importance of the environment in determining bodily changes. Each of these ideas are building blocks upon which others, including

Charles Darwin, stood. Darwin did, in fact, acknowledge Buffon's work in the *Origin* though he did not discuss it in detail (Eiseley 1958; Roger and Williams 1997).

Simultaneously, Swedish botanist Carl von Linnæus (1707–1778) contributed to the development of evolutionary ideas through his interests in classification and ecology. Linnæus' *Systema Naturæ* described all known plants and animals of the time and established the principles of modern taxonomy. Linnæus was more sophisticated than the previous scholars in his use of the terms genus and species, applied to specific levels in his hierarchical classification scheme, as he began with a careful description of species. Then, based upon morphology, he grouped species into genera, genera into orders, orders into classes, etc. *Systema Naturæ* was revised numerous times; the tenth edition (1758) included humans. This was important as, similar to Buffon's discussions of apes and humans, Linnæus explicitly recognized the structural similarities between humans and other animals. Humans were classified under the category Anthropomorpha along with nonhuman primates, bats, and sloths. This classification system has existed, virtually unchanged, for over two and a half centuries. While the Linnæan taxonomy was non-evolutionary, reflecting the static nature of life and unchanging species, it has been key to the development of evolutionary theory as we could not talk about evolution without widely shared and accepted names for genera and species. Darwin incorporated Linnæus' concepts both directly and indirectly via his discussions of nature and, of course, through use of the classifications (Eiseley 1958; Fara 2003).

The French Revolution

Following on the heels of Buffon and Linnæus and exemplifying the French Revolution period, Jean Baptiste Pierre Antoine de Monet, Chevalier de Lamarck (1774–1829), was one of the most outspoken intellectuals on the ideas of progress and change. He saw each species as embarked on a journey toward perfection with new species

created at the lower end of the scale by spontaneous generation; thus, there would be no gaps in the ascending progression of forms (Eiseley 1958). He was, in short, an evolutionist.

In *Philosophie Zoologique* (1809), Lamarck argued natural processes could result in radical change in an organism during its lifetime, and organisms could make unlimited progress, not only by adapting to local environmental conditions but also by moving up the evolutionary scale. He suggested that organisms were driven to perfection by an internal force, called vitalism. Somewhat similar to Aquinas' Great Chain of Being, he arranged species in a hierarchical order from one-celled forms all the way to humans; it was a linear and progressive hierarchy of complexity. It was evolutionary as he was addressing the transformation of species. He was the first to recognize the taxonomic importance of a vertebral column and use it as a taxonomic marker for species. He was also the first to use "biology" (*biologie*) to describe the new emerging science (Bowler 1996; Eiseley 1958).

Lamarck is remembered by most people for an idea that he did not originate, the development or atrophy of organs through use or disuse and the transmission of their condition to offspring. In fact, this idea of acquired characteristics was widely held among people at that time. The important point about Lamarck is his emphasis on change. He argued that the discontinuities in the progression of forms were due to local and gradual adaptations by each species to their specific environmental circumstances, achieved through the animals' volition. These ideas are particularly important in the development of evolutionary thought because Lamarck challenged the accepted dogma of the natural world as static (Eiseley 1958). Darwin read Lamarck early in his academic career – while investigating *Flustra* invertebrates and, later, beetles (Desmond and Moore 1991). Near the end of and following the French Revolution period, three distinct local intellectual traditions arose in Europe – French Environmentalism, English Natural Theology, and German *Naturphilosophie*. They, too, played a role in shaping Charles Darwin and modern evolutionary theory.

Environmentalism in France

The importance of the environment in sculpting all life forms had been recognized for roughly 1500 years pre-Renaissance, and the Renaissance conditioned people to expect new animals and plants in each new part of the world explored. Thus, by the 1700s, many viewed the environment as *the* primary factor in shaping all living forms. Environmentalism's influence on understanding the human condition reached an apex with the writings of Jean-Jacques Rousseau (1712–1778) in France. Rousseau developed the idea of the "noble savage," that people who lived away from civilization in simple tribes "with" nature were straightforward, self-sufficient, democratic, and honest. Rousseau built upon the work of Lucretius, speaking of the "noble savage" environment as an ideal against which humanity should continue to measure itself. He recognized that our species had changed physically over time, commented upon the struggle for existence, and discussed the concept of "perfectibility" that had no goal or design. The environmentalist tradition had considerable influence outside of France, and one of its most important supporters was Erasmus Darwin, Charles Darwin's grandfather (Bowler 1996; Eiseley 1958).

Natural Theology in England

Following upon the earlier work of John Ray, William Paley (1743–1805) more fully developed the idea of the perfection of living organisms. Paley's *Natural Theology: or, Evidences of the Existence of the Deity, Collected from the Appearance of Nature* (1802), begins by illustrating the argument from design and the existence of a creator. According to the doctrine of *Natural Theology*, everything in nature reflects the beauty and perfection of the god who designed it. Paley's work contributed to the natural theology position by collecting a large number of examples of the perfection of design. He is best known for his watchmaker analogy. *Natural Theology* was a best seller in its time and was read by Charles Darwin just after completing his

degree at Cambridge. In fact, Paley's works were part of the curriculum at Cambridge, and Darwin remarked upon how much he admired them (Desmond and Moore 1991; Eiseley 1958; Phipps 1983).

Naturphilosophie in Germany

At the same time that *Natural Theology* and *Environmentalism* were becoming popular in England and France, respectively, *Naturphilosophie* was growing in Germany. This approach emphasized observations and comparisons of diverse types of animals and plants with the goal of identifying features shared in common. *Naturphilosophie* saw all life as underpinned by certain basic archetypes (*Bauplans*), which have ever more perfect manifestations as one moves up the Great Chain of Being. Again, there were similarities here with ideas being expressed by Lamarck and previously by Linnæus. One of the co-founders of the *Naturphilosophie* tradition was Johann Wolfgang von Goethe (1749–1832). While Goethe is best known for his literary accomplishments, he was also interested in science and studied, among other things, anatomy. Goethe's observations provided support for ideas about the continuity of anatomical structures across species – as opposed to the uniqueness of humans. He, too, argued that animals are shaped by their environments (Goethe and Naydler 1996; Lovejoy 1936).

Outside of Germany, *Naturphilosophie* had a number of supporters. Among them was Richard Owen (1804–1892), England's most prestigious zoologist and paleontologist. Owen is remembered for a variety of paleontological discoveries; however, it is his careful definition of analogy and homology that is important to the development of evolutionary theory. The terms analogy and homology were widely used at the time, particularly in discussions of comparative anatomy, but they were often used synonymously. Owen clarified the differences based on form and function and believed that evolutionary processes were at work in the formation of species. Owen and Darwin worked together on the specimens Darwin brought back from his time on the *Beagle*

though they eventually parted ways due to Darwin's views on transmutation (Bowler 1996; Eiseley 1958).

The Darwins

The links across the centuries between these various approaches and theorists with Charles Darwin's theory should be apparent. There is almost 2000 years of discussion about the natural processes of organic change upon which Darwin would build. Thus, the stage for the development of Charles Darwin's theory of evolution was set. As can be seen from the preceding paragraphs, Darwin did not originate ideas about evolution, change, or the impact of the environment. Rather, he synthesized them and added much new supporting data. One family member, in particular, played a role in setting the intellectual stage and in laying the groundwork that would make Charles' lifestyle possible. This was Erasmus Darwin.

Erasmus Darwin

Charles Darwin's grandfather, Erasmus Darwin (1731–1802), attended Edinburgh Medical School and went on to become a very successful physician, accumulating the considerable wealth that would provide the financial base allowing Charles Darwin to pursue the life of a scientist/scholar. Erasmus Darwin's most important scientific work, a work that would establish him as the leading medical author of the day, was *Zoonomia: or, the Laws of Organic Life* (1794–1796). It marked the beginning of the Darwin family's interest in evolution. Erasmus was convinced that forms remotely similar to living ones were ancient and were their likely ancestors, based on a comparison of morphologies. He saw nature as dynamic and active; species were not static but ever-changing and developed structures that were most suitable to their environments. He also touched on the problems brought on by overpopulation and competition for resources; affirmed the close relationship between monkeys, apes,

and humans; recognized the importance of sexual reproduction in the evolution of species; and was concerned about male competition. Similar to Lamarck, the processes he described also incorporated the animals' volition. Thus, in *Zoonomia*, Erasmus Darwin laid the groundwork for many of the themes that Charles would go on to explore in-depth in either the *Origin* (1859) or the *Descent* (1871). Although Erasmus died before Charles was born, Charles familiarized himself with his grandfather's work at a young age and read it at least twice more over the course of his lifetime (Bowler 1996; Desmond and Moore 1991; Eiseley 1958; King-Hele 1999; Smith 2010).

Charles Robert Darwin

1809–1827

Charles Darwin (1809–1882; hereafter referred to as “Darwin”) received most of his early schooling from his sister, Caroline, particularly in Biblical studies, until joining his older brother at the Shrewsbury School at age 9. Most of Darwin's early education was unremarkable. He was a lackluster student, at best. However, there were several events throughout his teenage and young adult years that played roles in shaping the naturalist and evolutionist he would become. At age 16, he was sent by his father to Edinburgh to join his brother, Erasmus, who was studying medicine. Although Charles did not ultimately pursue a medical degree as his father desired, he did join a student society for the study of natural history – the Plinian Society – that was known for its radical and heretical ideas and discussions. Doing so introduced him to Robert Grant (1793–1874), a Lamarckian and avowed evolutionist, who mentored Darwin in both naturalist skills and evolutionary thinking. Grant pushed Darwin to read Lamarck while Darwin assisted Grant in investigating the status of marine invertebrates. It was Grant's teachings that shaped Darwin's approach to evolution years later. During his final year at Edinburgh, Darwin took a natural history course taught by Robert Jameson (1774–1854). This course granted Darwin access to the Edinburgh University museum, one of the

largest in Europe, where he spent considerable time learning historical geology. He also learned avian taxidermy there from John James Audubon. Both geology and taxidermy would serve him well on the *Beagle* (Bowler 1996; Desmond and Moore 1991; Eiseley 1958).

1827–1836

Darwin left Edinburgh in April 1827 and, early in 1828, went to Cambridge to study for the clergy, again at his father's insistence. As with the other institutions he attended, Darwin's career at Cambridge was largely unremarkable. However, he became enamored with beetles and developed a reputation for his beetle collection skills among fellow collectors. A significant event in Darwin's intellectual development occurred during his junior year when he got to know and became friends with John Henslow (1796–1861), Professor of Botany. Darwin took Henslow's botany course, and they went on field trips together, becoming close friends. Darwin's interests shifted from beetles to plants, and he wanted to follow in Henslow's footsteps. He also developed strong interests in traveling to distant lands. He was convinced that there were many new beetles, as well as other forms of life, to be discovered (Eiseley 1958). Darwin collected many plant specimens while on the *Beagle* specifically to send back to Henslow (Desmond and Moore 1991).

At the same time, Darwin was invited on a small geological expedition by Adam Sedgwick (1785–1873), a Cambridge geology professor. The expedition with Sedgwick lasted only weeks but served to further Darwin's interests in the wonders of geology. When Darwin returned to Cambridge, he found an invitation to accompany Capt. Robert Fitzroy (1805–1865) on a 2-year survey of coastal South America on the *H.M.S. Beagle*. Darwin went to London to meet with Fitzroy and discovered that the voyage aboard the *H.M.S. Beagle* was scheduled to last 3 years, not the originally proposed 2. In actuality, the journey lasted 4 years and 10 months (from December 1831 to October 1836), and the data, specimens, and observations Darwin collected while on the trip formed the cornerstone of all

his future work (Desmond and Moore 1991; Eiseley 1958; Keynes 2003).

1836–1839

Darwin arrived back at Shrewsbury on October 4, 1836, and set about the huge task of cataloging all the notes and the specimens he had collected during the voyage. He used Cambridge as his initial base of operations and started writing the official version of his diary, *Journal of Researches*, to be published by the British Admiralty. His first presentation in London on the geology of the coast of Chile was warmly received and impressed Charles Lyell (1797–1875), the preeminent geologist of the time. Darwin had read two volumes of Lyell's *Principles of Geology* (1830) while aboard the *Beagle* and later stated it had been a huge influence on him. They became lifelong correspondents. By March 1837, Darwin had moved from Cambridge to London where he continued writing his accounting of the journey and, in doing so, confronted the issue of the changing nature of species. Darwin had concluded that species were not fixed but could form new species gradually over long periods of time. By July 1837, he had begun working on notes about species change which he would call the *Transformation of Species*. These notes are important because they would later serve as proof of Darwin's priority to ideas about species change and evolution in his exchanges with Alfred Russell Wallace (Desmond and Moore 1991; Eiseley 1958).

The period from 1837 to 1839 was among the most productive in Darwin's life as it was then that his ideas regarding natural selection took root in a series of notebooks and manuscripts where he outlined his thinking about science, religion, and evolution. During this period, there were several critical points in his intellectual development. In September 1838, Darwin read Thomas Robert Malthus' (1766–1834) *An Essay on the Principle of Population* (1798) which played a powerful role in shaping Darwin's thinking about competition, population size, and species change. Malthus recognized that human population size

could increase geometrically, while food supplies could only increase in a linear arithmetical fashion, leading to competition, population crashes, and the struggle for existence. While these years were replete with intellectual excitement, Darwin was also keenly aware of the religious, social, and political implications of his ideas (Bowler 1996; Desmond and Moore 1991; Eiseley 1958).

1839–1857

Two and a half years after the return of the *Beagle*, Darwin published his first book. The *Narrative of the Surveying Voyages of His Majesty's Ships Adventure and Beagle* (1839) received generally positive reviews and served notice of the reception his future works would receive. It was also during this period that Darwin read two of Linnaeus' essays regarding the economy of nature. His next book, *Structure and Distribution of Coral Reefs* (1842) was a technical book that Darwin did not expect would have much circulation, and he was correct. By the spring of 1844, Darwin had expanded his notes started in 1837 into a full 189-page essay on evolution. He realized the power of his words and found himself in a quandary about publishing it. After considerable thought, he decided not to publish at that time and moved on to a new project on the geological observations he had conducted while on the *Beagle*. There was a growing interest in ideas about transmutation of species; although not popular in Charles' intellectual circles, evolutionary ideas were in the air (Desmond and Moore 1991).

The year 1851 proved to be an extremely important professional time for Darwin as he met Thomas Henry Huxley (1825–1895). Huxley served as surgeon and naturalist aboard the *H.M.S. Rattlesnake* for 4 years where he also studied marine invertebrates and published a number of influential papers. His association with Darwin was solidified after Huxley reviewed Charles' barnacle books (*Living Cirripedia*, 1851, 1854) and incorporated Darwin's observations into his own natural history articles. The barnacle work provided Darwin with the empirical evidence he felt he needed to convince the critics of

transmutation of species. His evidence for his arguments about the formation of new species was, by then, well-developed. His work on barnacles had convinced him that virtually every anatomical detail varied in some way and that this variation was a natural consequence of reproduction. He used homology among the various barnacles as key to understanding their evolutionary relationships and saw embryology as the key tool for discovering homologies. Here, he was building on Milne-Edwards' (1808–1885) influential work on comparative embryology and classification (Stott 2003).

Darwin next turned his attention to pigeons and chickens, reasoning that what occurred in nature regarding the production of variation also occurred with domestic animals. He became interested in “sports,” forms that differed in some way from the typical forms. He chose pigeons and chickens because of their existing variation, their availability, and abundant available information. It was commonly held among fanciers that each breed was distinct, originating from several wild stocks. Darwin set out to show that all varieties arose from a single common ancestor. Darwin was returning to the contentious themes of his notes and essay from 1837 to 1844, respectively; he was drawn to working on natural selection again. Thus, in the mid- to late 1850s, Darwin was applying his evolutionary ideas to vertebrates. However, he might never have published on these issues if not for the events of 1858 (Desmond and Moore 1991).

1858–1859

It was on June 18, 1858, that Darwin received a manuscript from Alfred Russel Wallace (1823–1913) entitled “On the Tendency of Varieties to Depart Indefinitely from the Original Type” asking Darwin to forward it on to Lyell if Darwin thought it worthy of Lyell’s attention. Wallace and Darwin were both committed to explaining the natural world and had corresponded previously, but it was not until Darwin received a copy of Wallace’s essay that laid out his view of evolution that Darwin recognized Wallace as a true

competitor. Darwin realized that Wallace was advancing a theory of variation and natural selection that was identical to his own. Within a week of receiving the paper, Darwin wrote both Lyell and Joseph Dalton Hooker (1817–1911), a preeminent English botanist, and asked their advice. Both Lyell and Hooker knew of Darwin’s work over the previous two decades, but Darwin knew both would be scrupulously fair in such a serious scientific matter. The question of priority was at stake (Darwin 1958 [1892]).

Lyell and Hooker recommended that Darwin and Wallace present joint papers together – part of Darwin’s 1844 essay and Wallace’s 1858 paper – at a meeting of the Linnæan Society in London. Thus, less than 2 weeks after Darwin’s receipt of Wallace’s paper, the Darwin-Wallace papers were added to the agenda. On July 1, 1858, the Secretary of the Linnæan Society read excerpts from Darwin’s essay, part of Darwin’s 1857 letter to Asa Gray where he repeated the themes of his essay, and Wallace’s paper to the 30 or so assembled members of the Society. Neither Darwin nor Wallace attended, but Lyell and Hooker both spoke, attempting to impress on the audience the importance of both papers. The combined Darwin-Wallace (1858) extract/letter/paper was published by the Linnæan Society on August 20, 1858. Darwin always referred to the work as “our theory.” Wallace, on the other hand, always gave Darwin priority (Desmond and Moore 1991).

Darwin immediately began working on an actual paper based on his essay, promised to Lyell and Hooker, but it quickly expanded into something much larger. He informed Lyell and Hooker that his paper, which was supposed to be ready in October to be published with Wallace’s paper, would have to be published separately, and he was negotiating with the publisher John Murray. By April 1859, *Origin* was at the printers. The corrected proofs were returned to the printer in October, and, on November 2, 1859, Darwin received a specimen copy of *On the Origin of Species by Means of Natural Selection or the Preservation of Favoured Races in the Struggle*

for *Life*. Over the next 2 weeks, Darwin sent a number of complimentary copies of the book to colleagues in Europe and the United States. To Darwin's surprise, all 1,192 copies (1,250 less the 58 complimentary copies) were sold to retailers on the first day of publication, November 24, 1859. The advertised price was 15 shillings (roughly the equivalent of \$83 today) (Darwin 1958 [1892]).

Darwin continued to be nervous about the reception his work would receive among scientists and, in particular, Charles Lyell who suspended judgment for an additional couple of years. On the other hand, Huxley's reaction was immediately enthusiastic. Once Huxley read the entire work, he recognized its monumental contribution. What impressed Huxley most was the quality of the scientific argument and the amount of biological and geological data that were explained by it. Darwin's ideas were, by far, the most plausible explanations for a variety of puzzling phenomena, and Huxley made it his mission to see that Darwin's ideas were heard. Huxley was acutely aware of Darwin's abhorrence of controversy as well as his own skill and appetite for it, so he immediately became Darwin's self-appointed champion. The publication of *Origin* in 1859 marked the beginning of a discussion about evolution that continues today (Darwin 1958 [1892]).

Conclusion

Over the remainder of his life, Darwin wrote books on the communication of emotion in animals, the role of sexual selection in human evolution, locomotion in plants, fertilization in orchids, variation in domestic animals, and the action of worms. His contributions to natural history and biology are without peer, and today Darwin stands as the greatest scientific thinker of the nineteenth century and one of the most brilliant scientists of all time. The preceding description offers some insight into the historical events that contributed to and influenced his thinking and works.

Synonyms

Casual sex; Hooking up

Definition

Sex that is not based on an emotional context or with a romantic partner.

Introduction

Impersonal sex cannot be oversimplified; instead, for impersonal sex to take place, a number of conditions must be met. Other factors, including the gender and race of the participants play key roles. There are also various reasons why someone may participate in impersonal sex, as well as both benefits and drawbacks of participation.

Impersonal sex, also called “hooking up” in modern culture, is sex that is not based on an emotional context or with a romantic partner. Impersonal sex is sexual intercourse with another person with many purposes including fun, to enhance one’s social status among peers, to assert control over one’s own sexuality, to express one’s sexual freedom, or to have sex without the intention of emotional commitment. These are the

factors used to represent an endorsement of the hookup culture (Aubrey and Smith 2013). In addition to the various reasons that people have impersonal sex, there are also a series of conditions that describe the ideal conditions for impersonal sex among men; women have not been described to the same extent. Weinberg and Williams (1975) describe conditions including having a “safe” setting or location in which the person feels private and does not put them in danger; having good sexual partners and/or good options at a low price (such as dating and hookup-oriented cell phone applications); a situation that promotes an organized reality between both parties in which both parties are on the same page about expectations; limited non-sexual interaction between the two parties outside of the sexual encounter; an ability to mask one’s feelings of rejection and non-harsh solicitation of sex or offers of sex; and a comfortable and relaxing physical setting. There are few studies conducted on the matter of impersonal sex, but they seem to focus on examining age’s role in and risk factors of impersonal sex. For example, some of these risk factors include a range of negative health indicators (Långström and Hanson 2006), with others reporting negative effects of sexual permissiveness on social acceptance (Vrangelova et al. 2014).

Gender appears to be the most common variable researched for its role in impersonal sex. In one study conducted by Monto and Carey (2014), the researchers drew respondents from the General Social Survey (GSS) who were between 18 and 25 years of age and who had attended college for at least 1 year from the year 1988 up to the year 2014 when they conducted their study. They looked at the number of sexual partners each person had since turning 18 and how many sexual partners they had had in the past year, how often they had had sex in the past year, and if the sex they had was with a regular partner, a friend, an acquaintance, a casual date, or hookup, or if the person fit none of those categories. They observed respondents from recent years did not report more sexual partners, more frequent sex, or more partners during the past year than earlier respondents had reported. Thus, these patterns or behaviors have not changed as a function

of time or across generations. However, when they explored gender differences, there were more women reporting sex in those earlier years than there were men. In addition to this difference between earlier and more recent participants, sexually active respondents from recent years were more likely to report sex with a friend and less likely to report sex with a spouse or a partner. This implies many people are leaning toward more casual and noncommittal sex in more recent years, and that men are reporting more sex than in previous years.

Another study conducted by Boot, Peter, and Oosten (2014) examined women’s responses to sexual media and how the personal factor of impersonal sex orientation, along with the situational factor of multitasking, affected their involvement with the media. Impersonal sex orientation refers to someone’s preference for uncommitted sexual relationships, and those who score high on this variable are more focused on appearances and physical satisfaction instead of on emotional closeness with another person. The women were asked to watch a sexual scene, and their involvement was measured by how similar they perceived themselves to be like the woman in the scene, how likeable they found that woman, and how much they wished they could be like her (i.e., wishful identification). Boot and colleagues found women high in impersonal sex orientation had decreased perceived similarity to the woman in the scene and found them less likeable when multitasking. On the contrary, those low in impersonal sex orientation found the woman in the scene more likeable while multitasking. In short, there was a significant interaction between media content and impersonal sex orientation on perceived similarity and wishful identification, as well as a significant interaction between media content, impersonal sex orientation, and multitasking on perceived similarity and likeability. Thus, women’s responses to social media content depend on their impersonal sex identification, *and* multitasking may increase or decrease the influence of sexual content depending on personal characteristics.

Spell (2016) investigated how gender and race impacted one’s participation in hookup culture.

She collected her data from interviews that she conducted herself, along with survey data collected from the Online College Social Life Survey. She argues the importance of both variables in understanding these phenomena. For example, Asian men and nonwhite women face additional barriers to participate in hookup culture compared to other groups, including physical stereotypes and possibly other stereotypes or racism-related concepts. Spell further argues that research must incorporate intersectionality to study hookups. Truly, the relationships between factors such as gender, race, and social class may better describe the nature of and preference for impersonal sex.

Vrangelova and Ong (2014) studied the benefits of casual sex as well the moderation of sociosexuality (described as one's personality orientation toward casual sex) on well-being. They describe the effects of casual sex on well-being as mixed; this is due to the moderating factor of sociosexuality. The positive effects as they described them include satisfaction, confidence, and self-knowledge and are stronger and more common results of casual sex compared to the negative outcomes (e.g., lower self-esteem, coupled with increases in depression, anxiety, and sexually transmitted diseases; Vrangelova 2015). The authors found that those who were sociosexually unrestricted reported higher well-being after casual sex than they reported without sex. On the other hand, those who were sociosexually restricted did not report much of a difference in their well-being before and after sex.

Conclusion

There is still room for additional research on the topic of impersonal sex, though we understand there are many factors that play a role in its frequency and effects. Some of these factors include the setting, one's own reasons for seeking impersonal sex, and the individual and their personal views on impersonal sex. Researchers note various ideal conditions to be met as well as positive and negative outcomes, such as getting praised by one's peers or getting rejected by peers for one's

sexual behavior. Individuals may experience casual sex differently, and its effects may vary in accordance with personal characteristics and preferences. For example, two people could experience the same encounter, but one person could respond positively and be happy with the result, while the other person may have disliked the event to the point of regret or self-loathing. Race and ethnicity, sexual orientation, and well-being appear to be critical factors in these investigations, each requiring additional research as these factors could potentially affect an encounter and its outcome. Overall, the widespread prevalence of impersonal sex necessitates additional research to better understand its impact on individuals and their relationships.

Implications for Pregnancy

Anastasia Makhanova
Florida State University, Tallahassee, FL, USA

Synonyms

[Gestation period](#); [Gravidity](#); [Parity](#)

Definition

A number of adaptations have evolved in women to deal with a tremendous set of physiological and psychological pressures during the 9-month gestational period and labor.

Introduction

Pregnancy lasts approximately 9 months and places many demands on women's bodies. First, growing a fetus is tremendously costly in terms of energy needs, and it also places physical strains on a woman's body. Second, pregnancy greatly

inhibits locomotion and makes women vulnerable to threats. This entry will address (a) the basics of pregnancy, (b) two hypotheses about the length of gestation, and (c) the psychological implications of pregnancy.

The Basics of Pregnancy

Gestation begins after copulation during a woman's fertile window when sperm fertilizes the egg. The zygote (fertilized egg) travels down one of the fallopian tubes as it undergoes rapid cell division before implanting into the uterine wall. For the next 10 weeks, during the first trimester of pregnancy, the embryo and all of the necessary structures for fetal development (placenta and umbilical cord) then develop. After this point, the embryo is typically referred to as a fetus.

Women typically carry only one fetus during a pregnancy, because usually only one egg is released from one of the ovaries during ovulation. However, sometimes women will carry multiples. Twins are most common and can either be dizygotic or monozygotic. Dizygotic (fraternal) twins result from two eggs being released and fertilized during ovulation. Monozygotic (identical) twins result from a single fertilized egg that splits early on in the pregnancy.

Women undergo several physiological changes to accommodate the pregnancy. Endocrinologically, women experience increases in both progesterone and estrogen throughout gestation. Further, women's immune systems become suppressed so that the genetically dissimilar embryo can develop without being rejected by the mother's body (Navarrete et al. 2007). Women typically gain weight during pregnancy as the fetus develops, the uterus enlarges, the placenta becomes filled with amniotic fluid, and the body retains extra fat and water. Although women typically do not start lactating until a couple of days after giving birth, women's breasts develop throughout pregnancy to be able to produce milk, and the areolae typically become larger and darker. Women's blood volume increases by up to 50%, and they experience a number of other cardiovascular and hematological changes.

Consequently, pregnancy brings several challenges. Women need to increase their protein and calorie intake in order to support the development of the fetus as well as all of the other necessary structures (e.g., placenta and other uterine structures, breasts). At the same time, pregnancy makes locomotion difficult, and women become more vulnerable due to the increased necessary effort (or potential inability) to acquire resources and avoid harm. Further, if things do not go well during the pregnancy, women may experience medical problems or can miscarry. Both of these outcomes are very costly.

Not only is the 9 months of gestation physiologically costly to women, but giving birth is also an ordeal. A birth is considered full-term if the gestational age of the fetus is 37–42 weeks. Modern humans and other hominins (extinct human species and all immediate ancestors including members of the genera *Homo*, *Australopithecus*, *Paranthropus*, and *Ardipithecus*) have birth canals that are different from other animals in that they are wider sideways (hip to hip, transversely) than front to back (anteroposteriorly). These physiological constraints mean that babies have to rotate as they are moving down the birth canal; first they face sideways to align their head with the birth canal and then they turn parallel to the mother for the rest of their body to move through the birth canal (Rosenberg and Trevathan 2002). The turning process necessary to align the infant's body properly with the mother's birth canal makes the birthing process more complicated.

Further, childbirth is usually painful and can be dangerous as babies' heads and shoulders are large in proportion to women's rather narrow birth canals. Unlike other primates for whom labor lasts about 2 h, first-time mothers typically are in labor for 9 h (Albers 1999), and about 1% of babies end up having shoulders too large to pass through their mother's birth canal (Rouse et al., 1996). Although this would have been deadly in ancestral times, this problem can be solved with a cesarian section and other modern medicinal interventions. Despite the physiological costs and risks associated with gestation and parturition (labor and birth), selection pressures on women's gestational length must have contributed to the

9-month duration of pregnancy. Several hypotheses exist to explain the length of women's pregnancies and birthing constraints. Two such hypotheses are discussed in detail within this entry: the obstetrical dilemma hypothesis and the energetics of gestation and growth hypothesis.

Hypotheses about Gestation Length

Humans have much larger brains than any other hominin. Consequently, heads of human babies are also large. Although most nonhuman primates are precocial (able to locomote and feed themselves almost immediately after birth) and humans are altricial (unable to locomote and feed themselves immediately after birth), the length of pregnancy is similar (Rosenberg and Trevathan 2002). There are several hypotheses that try to explain the timing of human gestation and birth (parturition). This entry will address the obstetrical dilemma hypothesis, which focuses on bipedalism and the narrowing of the birth canal, and the energetics of gestation and growth hypothesis, which focuses on the metabolic demands placed on the woman by pregnancy.

Obstetrical Dilemma Hypothesis

Human bipedalism and large brains can be seen as conflicting adaptations. Walking on two legs narrowed the pelvis and subsequently women's birth canals. These changes make it harder to give birth to babies with the larger heads necessary to accommodate and foster a large brain. Early hominin skeletons, like those of *Australopithecus afarensis*, show signs of bipedal locomotion. Therefore, at that point human ancestors had already started to undergo skeletal changes that made bipedalism possible, including those to the pelvis. However, the brain size in proportion to the bodies in *Australopithecus afarensis* was still small. It is proposed that later, around the time of *Homo erectus* (when brain size started increasing more rapidly), the birth canal, already narrowed from bipedalism, became a limiting factor to gestation. Like humans, *Homo erectus* infants were likely relatively helpless at birth, as indicated by the fossil record. Thus, the obstetrics dilemma

hypothesis suggests that bipedalism constrains the human gestational period such that the babies are born at this particular (and altricial) point of development because that is the point at which they are still able to pass through the birth canal. The result is an infant born with about 25% brain development of an adult human, almost half of that of nonhuman primates (Trevathan 2011). Two additional physiological adaptations allow for the birth of large-brained babies to bipedal mothers: (a) babies are born with soft cranial bones that continue to develop after parturition, and (b) women have greater hip width compared to men (who can be bipedal without having to give birth).

Energetics of Gestation and Growth Hypothesis

Although human pregnancy is in the same temporal range as that of nonhuman primates, human infants are born at a much earlier developmental stage. They require constant care because they cannot walk, eat, or protect themselves from predators, and they depend fully on their parents for survival. Having this parental role and the associated division of labor adds to both mothers' and fathers' costs associated with reproduction. Is bipedalism the only benefit or constraint associated with pregnancy length? If humans didn't walk upright or have wider pelvises, would they have a pregnancy double in length? To match the gestational development of infant chimpanzees, women would have to sustain an 18–21 month pregnancy (Portmann 1990).

Pregnancy is costly to women's metabolic processes, and greater fetal size would lead to even more energy expenditures. Thus, women may not be able to physically sustain a pregnancy necessary for the fetus to have a more developed brain. The energetics of gestation and growth (EGG) hypothesis argues that labor occurs when women are at the limit of their feasible energetic investment into the pregnancy. Dunsworth et al. (2012) examined infant body and brain size in relation to maternal body size (which is associated with the amount of metabolic resources the mothers have available) and found that brains of human infants relative to their mothers' bodies are larger than brains of infants of nonhuman primates. Thus, although infants are born altricial and with brains

at 25–30% of development, human mothers actually invest more metabolically in gestation than nonhuman primate mothers. Further, by the sixth month of pregnancy, women's basal metabolic rate is double what it was prior to pregnancy. The EGG hypothesis suggests that pregnancy length is directly related to the balance of infant metabolism demands and maternal metabolism capabilities. It would not have been adaptive for women to further invest energy into developing an offspring at a point where their own ability to survive and pursue other important goals would be jeopardized.

Psychological Implications

As discussed in the first part of the entry, pregnancy has immense physical costs. Women's energetic needs are doubled. Further, women become more vulnerable to pathogens because their immune system is suppressed. Especially in the latter parts of pregnancy, it becomes more difficult to move around to gather resources and escape threatening situations. Thus, women in ancestral times would have benefitted from developing different strategies for pursuing their goals when pregnant. This entry will discuss several lines of research in evolutionary psychology that examine these psychological adaptations.

Disease Avoidance

During pregnancy, the mother's immune system is suppressed in order to tolerate the genetically different embryo developing inside of her. The suppression is especially strong during the first trimester of pregnancy. Thus, women (and particularly women in the first trimester) are especially susceptible to pathogen contagion. Moreover, disease is especially pernicious at this stage because it can interrupt fetal development and result in severe issues. Therefore, women who were extra cautious in regard to what and with whom they came into contact would have had healthier offspring and increased fitness compared to women who did not regard their environment with due caution.

People's general psychological mechanism for avoiding disease – the behavioral immune system or behavioral prophylaxis – should therefore be

especially active during this vulnerable time. Indeed, women demonstrate an increase in disgust and aversion to potentially contaminated food in the first trimester of pregnancy over and above any effects of nausea and physical ailments (Fessler et al. 2005). Thus, women are more cautious of what they consume in the early stages of the pregnancy when they are most vulnerable and when it would be most problematic for them to be sick. Additionally, women's disgust reactions to food seem to be specific to foods that are novel and/or more likely to lead to contagion and that are not nutritious dietary staples (Mckerracher et al. 2015).

Further, certain people also pose contagion-related risks. Members of dissimilar groups likely have been routinely exposed to foreign pathogens, and coming into contact with these outgroups may result in contagion. Again, women in the first trimester demonstrate an increased preference toward members of their own groups and weariness of dissimilar individuals (Navarrete et al. 2007). Thus, it seems that women have adapted to be more cautious of pathogens during pregnancy (especially the first trimester).

Motivation to Affiliate

Humans face another set of pressures associated with giving birth that is absent for monkeys and great apes (Rosenberg and Trevathan 2002). For the latter, the infant is born facing the same direction as the mother, who can then easily reach down and assist herself in the process of navigating the infant toward her chest. Human babies are born facing the opposite direction as the mother, who then cannot assist herself as the infant is emerging because that would require bending the infant backward. Coincidentally, women are unlike most mammals in that they do not typically give birth in solitude. It may be that women who were more motivated to affiliate (perhaps because of fear and anxiety) had more successful births (i.e., fewer complications for themselves and the infant) due to the assistance they were able to secure. These pressures may have resulted in an evolved preference for social birth and midwifery.

Consistent with the increased need for assistance during birth and the vulnerability to threats pregnant women face during both gestation and postpartum, research suggests that pregnant women

may engage in nesting behavior as a way to protect themselves from these threats. Specifically, pregnant women prepare their physical and social spaces during pregnancy (Anderson and Rutherford 2013). Like other altricial mammals, human mothers begin preparing their physical space for the infant and do so more during the last trimester of pregnancy. Importantly, women also engage in social nesting behaviors by becoming more socially selective in their affiliation. This behavior serves multiple purposes. First, women are able to build closer networks by reinforcing relationships with their selected friends and family, who can later assist with labor and alloparenting (parenting or caretaking of the infant by anyone other than the parents). Further, by staying away from strangers and novel social environments, women are able to reduce their chances of encountering both physical and contagion threats. These nesting behaviors are not simply due to anxiety, mood, and energy levels (Anderson and Rutherford 2013).

Conclusions

Pregnancy requires a lot from women, and giving birth is further complicated by pelvic changes due to bipedal walking. Pregnant women have greater physiological costs and face heightened threat from disease, other groups, and complications. To mitigate these dangers, pregnant women engage in avoidant behavior of possibly threatening objects and people as well as selective affiliation to strengthen their social support.

Implications of Gossip

► Social Consequences of Initiating Gossip

Implications of Object Permanence

Richard Bogartz
University of Massachusetts Amherst, Amherst,
MA, USA

Definitions of Object Permanence

- (a) Knowledge that an object continues to exist when there is no longer sensory input from the object.

- (b) A sensorimotor organization of schemes, completed by about 18 months of age, that enables the infant's organization of reality into a world of objects, including the infant as one of them. – Piaget.
- (c) Inference, that an infant knows innately or early that objects exist when occluded, based on longer infant looking when an inferred expectation, resting on the assumption of that knowledge, is violated, and on additional assumptions that violation of expectation results in surprise and surprise results in longer looking.

Practical Implications of Object Permanence

Knowing that something exists when not perceived implies that the knowledge exists free of sensory input and suggests it can be used mentally without sensory support. The knowledge has been freed from the limitations and constraints of time, space, and perception. The knower no longer needs perceptual contact with the known for knowledge to exist. Such liberated knowledge underlies mental manipulation of the world, imagination, expectation, memory, and prediction.

Before object permanence, when knowledge depends on, and is essentially equivalent to, perception, disappearance of the object is disappearance of the knowledge. Out of sight is literally out of mind. The difference resembles the difference between following an argument and understanding it. Following requires presentation in some way, such as spoken or written, and depends on engagement with each step of the presentation. Understanding means one can know it without it being presented. It is independent of perceptual processes. Following requires a certain level of comprehension but does not ensure that knowledge endures after presentation ends. Understanding liberates knowledge from perceptual engagement. Object permanence is the analog of understanding with respect to knowledge of the existence of objects and events.

With object permanence, objects can exist in memory, serve prediction, and also

imagination. Object memory, predicting how an object will behave, or imagining what an object might be doing, all require objects that are mentally freed from perception. Object permanence enables mind to transcend the actuality of here and now. The child with object permanence can watch someone drive off in a car but know that the person continues to exist, or watch an airplane fly into a cloud and expect it to emerge. In the predator–prey relation, prey goes behind a tree or a rock but still exists for predator. From prey’s perspective, predator is no longer in sight but is still a problem. Where object permanence is limited, fear maintained by body chemistry can support continued flight even when the out of sight predator may not be mentally represented. Object permanence helps both predator and prey to survive.

Theoretical Implications of Object Permanence

Piaget (1954) introduced object permanence. He discovered that when an object is concealed, 5- and 6-month-old infants seem to no longer be aware that it exists.

In Piaget’s theory, schemes are cognitive structures for assimilating reality and enabling generalization of action to similar situations. Knowledge of the continued existence of objects that are no longer visible results from a progression of schemes, i.e., coordinations and organizations of looking and reaching.

Piaget found that the 9-month-old could remove an occluder to reveal a recently hidden object but still lacked some of the visual-motor coordination that would define complete object permanence. Along the 18-month or so path to completing the sensorimotor stage of development where the child structures the world and itself into a collection of permanent objects, the child succumbs to and then solves a series of puzzles, including the well-known A-not-B problem. If an object is hidden at location A, and then, as the infant watches, is moved to and concealed at location B, when the infant is allowed to reach for the object, reaching occurs

to location A. By 12 months, the infant reaches directly to location B.

By 18 months, the system of coordinations of visual-motor schemes is sufficiently complete for the infant to organize its world into objects that exist independently of action and perception, including the infant itself as one of those objects. As the child constructs reality by comparable coordinations involving space, time, and causality, it is gradually freed to grasp an external world of which it is a part.

From Piaget’s perspective, object permanence implies the completion of the sensorimotor stage of cognitive organization.

Nativist and Other Challenges to Piaget

Might the 5-month-old or younger, in a competence–performance contradiction, know that occluded objects continue to exist but be unable to display that knowledge because it does not yet have the required eye–hand coordination? The child knows but cannot display the knowledge. If so, introduction of a task that does not require removing an occluder might reveal object knowledge at an earlier age than claimed by Piaget.

Bower (1966, 1967) studied this possibility, and Bower et al. (1971) used a visual tracking task in which 20-week-old infants watched an object pass behind an occluding screen and then shifted their gaze to where the object would be expected to appear. If a different object appeared, this disturbed tracking. These findings suggest representation of an occluded object exists earlier than Piaget supposed. But Bower and Patterson (1973) showed that visual tracking movements continued even when the moving object was halted in plain sight, indicating a possible inertial component to tracking rather than occluded object representation.

Baillargeon et al. (1985) habituated 5-month-old infants to rotation of a drawbridge-like screen and then placed a block behind the screen. The infants were shown trials where screen rotation stopped at the point where the block would have kept the screen from further rotating, and trials where the screen seemingly rotated right through the block. In

both trial types, the screen reversed its trajectory revealing the block remaining where it had been placed. Longer looking to the “impossible” event was attributed to surprise resulting from violation of expectation of the block still being there and preventing complete screen rotation. The authors take this to reveal a form of object permanence occurring much earlier than Piaget predicted. Other studies are taken to support this finding (e.g., Baillargeon and Graber 1987).

Spelke and her associates (e.g., Spelke et al. 1992) have argued for innate core knowledge such as movement continuity and object solidity that enable the above apparent object permanence in the very young infant.

Baillargeon frequently invokes high level cognitive processes such as representation, assumption, expectation, surprise, belief, reasoning, inference to explain results in violation of expectation experiments with young infants.

Piagetian theory says that object permanence develops slowly as a result of interaction with the world and the organization and coordination of schemes. The implication of the nativist position with respect to the early occurrence of object permanence is that the Piagetian formulation of the development of object permanence may be wrong and raises doubts about the entire theory.

Challenges to the Nativist Position

The Perceptual Processing Response

Brilliantly challenging the nativist position, Haith (1998) argued that “Since virtually all of the nativist claims for early cognitive processes hinge on how long an infant looks at one display rather than another ... investigators who pursue high-level cognitive constructs must play the default game. That is, one must fend off every possible perceptual interpretation of differences to entertain default cognitive interpretations,” and this will involve many factors that affect looking, including variations in the perceptual dimensions of objects and people, familiarity, novelty, recency, predictability, and the time lapse between stimulus exposures. Haith cites numerous studies that call into question nativist high level cognitive

interpretations (e.g., Bogartz et al. 1997; Cohen, 1995; Cohen et al. 1996).

Bremner et al. (2015) provide another excellent alternative to the nativist position. “Rather than advance object persistence as an innate principle through which events are interpreted, ... persistence is specified by perceptual events such as deletion and accretion, and the developmental question is about infants’ changing ability to perceive object persistence on the basis of these cues.”

Parsimony claims abound. One response from Baillargeon (2000) has been to argue that greater parsimony results from attributing higher level processes to the infant, as opposed to detailed analyses calling for multiple explanations when perceptual processing analyses of the behavior are proposed. One counter to this claim is that it is not parsimonious to attribute higher level processes where lower ones will do.

The Dynamic Systems Approach

Another parsimony counter to the nativist claim is implicit in the Dynamic Systems approach of Schöner and Thelen (2006). They “offer a dynamic field model of infant visual habituation, which simulates the known features of habituation, including familiarity and novelty effects, stimulus intensity effects, and age and individual differences” and “provide simulated visual input of varying strengths, distances, and durations to 2 coupled and interacting fields. The 1st represents the activation that drives ‘looking,’ and the 2nd, the inhibition that leads to ‘looking away,’ or habituation.” By varying the parameters of the field, the authors simulate the time course of habituation trials and show how these dynamics can lead to different depths of habituation, which then determine how the system dishabituates. The authors use the model to simulate a set of influential experiments by Baillargeon (1986, 1987a, b) using the well-known “draw-bridge” paradigm. The dynamic field model provides a coherent explanation without invoking infant object knowledge. “And importantly for the parsimony argument, the authors show that small changes in model parameters can lead to qualitatively different outcomes. Because in typical infant cognition experiments, critical

parameters are unknown, effects attributed to conceptual knowledge may be explained by the dynamics of habituation.” Thus, dynamic systems theory provides a rationale for why multiple explanations are necessary in perceptual processing analyses of the behavior that nativist claim indicate object permanence.

Schöner and Thelen (2006) indicate that all that the Violation of Expectation studies definitely show is that the infants notice a difference between the two events they have been shown. Everything else is an extrapolation from this. Schöner and Thelen argue that there are many reasons why infants might prefer looking at the “impossible” events. For example, in the “drawbridge” study, the “impossible” event involves more movement than the “possible” event. They conclude that Baillargeon has mistakenly assumed that the only difference between her stimuli is that one is “possible” and the other is “impossible.” However, there are actually many differences between the two stimuli, any of which might be the reason why infants look more at one than the other. What Baillargeon and Spelke claim is evidence of innate or early knowledge of the physical world, Schöner and Thelen say is no more than the effect of confounding variables.

Conclusion

The practical implications of object permanence are that knowledge and understanding of a world filled with objects and events require the ability to represent such a world in the absence of sensory input. The theoretical implications of object permanence and its time course concern which of various theoretical approaches to cognitive development hold the most promise for enhancing our understanding of the transformations that take the fetus and build it into the scientist.

Synonyms

Grandparental care; Grandparental involvement; Grandparental solicitude

Definition

Grandparental investment can be defined as all actions that may increase grandchildren's fitness at any opportunity cost to grandparents' own fitness. Grandparental investment includes conscious and unconscious investments grandparents channel toward their grandchildren. Grandparents can invest in their grandchildren either directly or indirectly via a third party (mostly via grandchildren's parents). Grandparental investments include, for instance, contacts with grandchildren, care, financial help, emotional support, and practical help. Evolutionary importance of grandparental investment refers to fitness benefits that grandparents may gain by providing support to their offspring. By investing in their grandchildren, grandparents can increase their own inclusive fitness (i.e., spreading their genes in future generations) by two important ways. First, by investing in their offspring, grandparents can boost parental fertility. Second, grandparental investment may increase grandchild health, well-being, and survival.

Introduction

Because of the demographic changes, grandparents today have a potential to be more important for child well-being than ever before. Increased life expectancy in modern Western countries means that grandparents and grandchildren have more shared years than before. Decreased fertility rates in turn denote that grandparents have fewer grandchildren, and thus they may be able to invest more in any particular grandchild. Regardless of this, grandparental effect in contemporary societies tends to be relatively small.

Grandparental Importance in Past and Present Societies

In premodern and historical populations, grandparental effect is measured by grandparental presence in same household or same village with their offspring rather than grandparental investment per se. In these populations grandparental presence is often found to correlate with both improved parental fertility and grandchild survival. However, all grandparents are not found to have similar effects. Studies have shown that paternal grandparents may improve fertility more than maternal grandparents (Sear and Coall 2011). In contrast, maternal grandmothers tend to increase grandchild survival more than maternal grandfathers or paternal grandparents (Sear and Mace 2008). These results can be explained by different sex-specific reproductive interests between women and men, which can be expanded to maternal and paternal grandparents (Euler 2011). Although, in several studies grandparental presence is found to benefit parents and grandchildren, kin relations include also conflicts. If grandparents push higher fertility and shorter birth intervals in females, this may have detrimental effects for both parents and grandchildren (Mace and Sear 2005). Moreover, in older age grandparents can be net consumers rather than net producers and could compete over local resources with grandchildren. This competition, in turn, may

have detrimental effects for grandchildren (Strassmann 2011).

Grandparental investment can still be associated with parental fertility and grandchild well-being in modern Western societies. In the case of parental fertility, the existing evidence is, however, scarce and mixed. While some have found that grandparental investment is associated with increased fertility (e.g., Tanskanen et al. 2014), some others have not detected such an association (e.g., Aassve et al. 2012). Moreover, the form of grandparental investment is found to influence the results. For instance, a study from the UK found no association between grandparental child care help and parents' childbearing, although emotional closeness between parental and grandparental generations was associated with improved fertility (Waynforth 2011). In contrast, a study from the Netherlands showed that grandparental support with child care was indeed associated with parental childbearing (Kaptijn et al. 2010).

In modern affluent countries, grandparents are not needed to keep their grandchildren alive as much as they were in subsistence societies. However, in present-day societies grandparental investment can still benefit grandchildren by improving grandchild well-being measured by, for instance, early years development, school success, and psychological well-being (Coall and Hertwig 2010). In particular, research has shown that in the cases of parental divorce, severe illness, and other family instabilities, grandparents can provide a buffer against these potentially harmful events (Sear and Coall 2011). As it was in pre-modern and historical populations, also in present-day societies, all grandparents tend to not benefit grandchildren similarly. In contemporary societies maternal grandparents are often found to improve grandchild well-being more than paternal grandparents (Sear and Coall 2011). Although in past populations the importance of grandfathers was small, in modern societies grandfathers may have as beneficial effect on grandchild well-being as grandmothers, at least in some circumstances (Sear and Coall 2011).

Conclusion

Evidence from both past and present societies shows that grandparents often boost parental fertility and child well-being. However, in some circumstances grandparents tend to have no effect at all, or they may have even detrimental effect. Thus, more research is needed to show in what circumstances grandparental investment may increase and in what circumstances decrease parental fertility and child well-being.

Importance of Maternal Grandmother

Alexander Pashos

Max Planck Institute for Social Anthropology,
Halle (Saale), Germany

If one asks people which of their four grandparents provided the most care for them when they were a child or to which grandparent they feel closest, the most people will answer the maternal grandmother.

Indeed, many research studies found that the intensity of caregiving by the four grandparents is not the same but regularly different. In most urban societies, grandmothers typically invest more in grandchildren than grandfathers, and maternal grandparents invest typically more than paternal. Thus, grandparental caregiving (i.e., their grandchild care, investment of resources, solicitude, involvement, and contact frequency) follows the asymmetric pattern: maternal grandmother provides on average the most caregiving for grandchildren, followed by the maternal grandfather and the paternal grandmother, and the paternal grandfather provides the least caregiving (Smith 1988; Euler and Weitzel 1996; Salmon 1999; Pashos 2000; Pashos and McBurney 2008; Danielsbacka et al. 2011; Pashos et al. 2016). The same asymmetric pattern exists also for emotional closeness: on average, grandchildren are closest to the maternal grandmother and least close to the paternal grandfather (Russell and Wells 1987; Laham et al. 2005; Pashos and McBurney 2008; Pashos et al. 2016). The asymmetric pattern cannot be explained by the different survival chance or age of the grandparents that follows the same

order (the maternal grandmother is on average the youngest; the paternal grandfather is the oldest), as analyses have shown (Euler and Weitzel 1996; Pashos 2000). Also residential distance, which in general strongly affects the grandparental caregiving, does not explain the caregiving biases. Same is true for other potential confounding factors which are however only inconsistently found, such as birth order, parent age, and grandchild age (for an overview, see Euler 2011).

Grandmother Hypothesis

Also in anthropological studies that deal with the evolution of grandparenthood, the maternal grandmother plays a central role. The classical grandmother hypothesis, also called prudent mother hypothesis, assumes that menopause has evolved in humans to stop the risky female reproduction in older age, in favor of investing in already existing children or grandchildren. According to Kristin Hawkes' newer version of the grandmother hypothesis, grandparenting along with longevity evolved through the grandmothers, who helped their daughters with provisioning the offspring (Hawkes et al. 1998). A number of studies using medical health data (Sear et al. 2000) or historical data (Sorenson Jamison et al. 2002; Beise 2005; Ragsdale 2004) found support for this view. These studies found lower child mortality or a better nutritional status in families where the maternal grandmother was present. In a German study, using historical data from Frisia, the paternal grandmother had even a negative effect on child survival (Volland and Beise 2002). However, other research studies revealed a rather mixed picture. Although most studies showed indeed positive effects for maternal grandmothers regarding child survival, some studies also found positive effects for paternal grandmothers, maternal grandfathers, or other kin, and some studies could not find a particular significance for any grandmothers (Sear and Mace 2008; Strassmann and Garrard 2011). Leonetti et al. (2005), for example, found a positive effect of the maternal grandmother, for maternal health, and child survival among the matrilineal Khasi.

However, among the patrilineal Bengali, they found a positive effect of the paternal grandmother on their daughter-in-law's fertility. From an evolutionary point of view, these mixed results might however very well represent different reproductive strategies. The maternal grandmother is biologically related to both her daughter and her grandchildren and hence also interested in her daughter's health, whereas the mother-in-law's reproductive interest is to invest in further grandchildren, however, not in her genetically unrelated daughters-in-law.

Maternal grandmothers were often found to be related to lower child mortality and this has been usually associated with their grandchild investment. However, cross-culturally they are not always the most important kin investors. In patrilocal societies, for example, maternal grandmothers do not live close to their grandchildren. Furthermore, many grandmothers are already deceased when grandchildren grow up. Some researchers therefore criticized the grandmother hypothesis in general, stating that the role of grandmothers may be overestimated. Their research results showed the importance of males for the provision of food and not the importance of grandmothers (Hill and Hurtado 2009). As an alternative for the grandmother hypothesis, also a patriarch hypothesis was proposed that assumes the evolution of longevity through males and not through females (Marlowe 2000).

Nevertheless, there is a relatively broad scientific consensus that extended kin members such as grandparents can be significant family helpers. Compared to other species, humans have a prolonged childhood, and it requires many resources to raise children to adulthood. Thus, in an ancestral environment, additional family helpers appear to be essential for the mother. Because in mammals most frequently the mother is the only caregiver, these additional offspring-care helpers are often called allomothers in biology, i.e., individuals other than the mother providing childcare. Anthropological research in traditional societies has shown that these caregivers can be typically fathers, older siblings and grandparents, or any other related or unrelated adults (Crittenden and Marlowe 2008; Kramer 2010). Sarah Hrdy

(2005), moreover, argued that humans could be classified as cooperative breeders. In a Pleistocene environment, two parent alone are not sufficient for bringing up offspring. Humans are rather characterized by a network of kinship members providing allomaternal assistance. In her view, help from fathers may be important but unreliable. For Hrdy, female helpers are even more important than male helpers; the most beneficial allomothers are, however, experienced elderly females, especially the maternal grandmothers.

For the consideration of maternal grandmothers as important caregiving helpers, not only nutrition and survival of infants should be taken into account. Also, help with childcare itself (Crittenden and Marlowe 2008) or to take responsibilities for children is already an important offspring investment. On the Trobriand islands, for example, it has been found that it is most often the maternal grandmother or other matrilineal kin (i.e., maternal aunts), who adopt children who became orphans (Schiefenhövel and Grabolle 2005). Also in Western countries, fostering roles were typically most frequently taken on by maternal grandmothers (Perry et al. 2014).

Paternity Certainty Hypothesis Explanation

A mother always knows when a child is hers, a father does not. The average degree of relatedness between a grandparent and a grandchild is $r = 0.25$, or, in other words, 25%. According to the rules of kin selection, under identical framework conditions, all grandparents should thus invest equally in grandchildren. However, due to the male uncertainty of relatedness in the family lineages, the average degree of relatedness to the grandchildren can vary. Therefore, Smith (1988) predicted and found that grandparental investment in grandchildren should be biased: (1) Grandmothers should invest in grandchildren more than grandfathers because of the grandfathers' paternity uncertainty. (2) Grandparents should invest more in daughters' children than in sons' children (i.e., invest more as maternal grandparents than as paternal grandparents)

because of the sons' paternity uncertainty. (3) In combination this means, grandparental investment in grandchildren should follow the order: maternal grandmother (highest investment), maternal grandfather and paternal grandmother (being in the middle), and paternal grandfather (lowest investment, because two times affected by paternity uncertainty).

Russell and Wells (1987) presumed the same differences when they measured in a questionnaire study students' feelings of closeness to parents and grandparents. The authors tried to estimate the level of paternity confidence by equating the measured differences in closeness mathematically with a factor for paternity uncertainty. In so doing, they calculated an average paternity confidence level of $p = 0.874$. In other words, they estimated 12.6% paternity uncertainty. Gaulin et al. (1997) used a similar method and estimated the paternity uncertainty between 9% and 17% for the grandparental caregiving results of Euler and Weitzel (1996). Because, the paternity uncertainty in the Western world was often estimated at that level then, the paternity certainty explanation became quickly popular. Newer studies, however, have estimated the level of actual paternity uncertainty in Western societies much lower, presumably less than 1–3% (Anderson 2006). Moreover, other researchers could not confirm an influence of actual paternity certainty in a society on measured caregiving biases. They therefore interpreted the universal asymmetric caregiving pattern as a reflection of paternity certainty in the environment of evolutionary adaptedness (EEA) rather than by current paternity confidence (McBurney et al. 2002). Reluctance in child caregiving might also be a result of a general tendency of mistrusting men's paternity, which has evolved in order to avoid misinvestment in genetic unrelated individuals. Reluctance in investing in patrilineal descendants might be a result of this general tendency of mistrusting paternity.

Although direct kin recognition mechanisms for detecting kinship such as phenotype matching might exist in humans, from a proximate point of view, the caregiving differences between the grandparents appear to be too great to be only

explained by actual paternity uncertainty. Some authors thus also have expanded the paternity certainty explanation by other explanations such as a sex-specific reproductive strategy which explains an additional bias in favor of daughters' children (Euler and Weitzel 1996; Euler 2011).

Stronger Matrilineal Family Ties as Explanation

In explaining why in particular maternal grandmothers are the most prominent caregivers, however, it is not necessary to assume that differential investment by grandparents is triggered by underlying mechanisms of detecting the certainty of relatedness to a grandchild. The caregiving biases can also be interpreted on a proximate level as a result of stronger matrilineal family ties, which create pathways for discriminative or preferential kin investment (Pashos 2000).

Research results show that women generally have closer ties to their families than men have to theirs (Salmon 1999). Thus, matrilineal family connections are stronger than patrilineal. In particular, the strong relationship between mothers and maternal grandmothers was found to reinforce biased caregiving to a significant degree (Chan and Elder 2000; Pashos 2000). However, also in general, the grandparent-parent and the grandparent-grandchild closeness were found to be interrelated (Michalski and Shackelford 2005). Moreover, the quality of the grandparent-parent relationship can explain the asymmetric grandparental caregiving to a great extent (Monserud 2008; Pashos and McBurney 2008). In addition, the relationship dyad between the daughter-in-law and the mother-in-law is on average the least good of all parent and grandparent relationships (Euler et al. 2009; Lee et al. 2003). This additionally increases the matrilineal bias. If, however, the relationship between the mother and her mother-in-law (i.e., the paternal grandmother) was good, grandchildren were found to have closer feelings to their paternal grandmother (Monserud 2008).

These research results fit very well with the proximate explanation of stronger matrilineal family ties as cause and not as result of

asymmetric caregiving. Because the relationship of a woman to her parents, especially to her mother, is more intimate than to her parents-in-law, and is more close compared to a man's relationship to his parents, a mother brings her children into closer contact with her parents than her husband with his parents. A frequent contact between grandparents and grandchildren enables the development of social closeness which allows or triggers the emergence of emotional closeness and grandparental caregiving through evolutionary mechanisms (Pashos and McBurney 2008). Therefore, caregiving by maternal grandparents, especially by the maternal grandmother, is stronger than that by paternal grandparents.

In the social sciences, similar explanations have been proposed and discussed to explain the asymmetric grandparent-grandchild relationships, however, usually ignoring or rejecting evolutionary influences on human kinship behavior. The parents, in particular the mothers, are seen as mediators or gatekeepers, who can build a bridge or also a barrier between the grandparents and the grandchildren (Chan and Elder 2000). Alternatively, women have been described as kinkeepers, who hold the family networks together. In this view, matrilineally biased intergenerational relationships are seen as a result of the female kin keeping, in which gender is not only relevant for parents but also for grandparents and grandchildren (Dubas 2001; Monserud 2008).

Maternal Grandmother and Divorce

The caregiving by grandparents who live together as a couple, as well as their contact frequency with grandchildren, is higher than by grandparents who are divorced. This effect is in particular true for the grandfathers (Euler and Weitzel 1996; King 2003), whose grandchild caregiving might be positively influenced by the coresident grandmothers (Gaulin et al. 1997). Maternal grandmothers, however, play a special role when it comes to a separation of a grandparent couple. Pashos et al. (2016) found that divorced grandmothers, as maternal grandmothers, did not show a reduction

of kin investment in daughters' children, however, as paternal grandmothers, did invest less in sons' children. This means that the caregiving by divorced grandmothers was even more biased in favor of their daughters' children; in other words, the matrilateral bias was greater. Interestingly, when grandmothers were remarried after divorce, their new husbands mirrored this discriminative matrilateral behavior of the grandmothers pretty strongly (Pashos et al. 2016).

Cultural Variety

The asymmetric grandparental investment pattern is very reliable to measure. It appears to be quite universal in all urban Western societies. However, in rural or more traditional societies also cultural variation in the asymmetric order of grandparental caregiving has been found. In rural mainland Greece, a traditional patrilocal society, paternal grandparents, especially paternal grandmothers, provided more caregiving than maternal grandparents, whereas among urban Greeks, the universal matrilineal caregiving pattern was found (Pashos 2000). Also in the USA, for rural farmers in Iowa, it has been found that grandchildren had more frequent contact with their paternal grandparents and received more help from them as compared to grandchildren from urban Southern California (King et al. 2003). Paternal grandparents who take on the duties of caregiving have also been documented for further countries, for example, rural China (Kaptijn et al. 2013).

Even if one assumes a higher paternity certainty for patrilocal societies where mothers-in-law can exert control over daughters-in-law, the paternity certainty hypothesis can only explain matrilineal biases in kin investment. A patrilinear or patrilinear bias in itself cannot be explained using this theory, because in a society with high paternity certainty, all asymmetric biases should disappear (Pashos 2000). Therefore, additional evolutionary explanations for the investment in sons and grandsons must be proposed, such as the Trivers-Willard hypothesis (Pashos 2000; Pashos and McBurney 2008).

Conclusions

Maternal grandmothers play a prominent role as kin caregivers in urban modern societies. In traditional societies, however, also paternal grandparents can take the place of the maternal grandmother as most important caregivers. Differing cultural rules can superimpose the strong, universal matrilineal family ties. Anthropological studies have shown the need for family helpers in rearing and raising children, what highly likely also led to the evolution of grandparenthood. The mother's mother appears to be especially predestined for this role, because she has not only a reproductive interest in helping her grandchildren but also in helping her daughter to whom she is related, as well.

Definition

The process through which early behavior pattern becomes restricted to a particular type of object as a result of a relatively brief exposure of that object at a particular early life stage.

Introduction

After some animals are born or hatched, they have the instinct to acquire or learn the behavioral characteristics from the object exposed to them. This kind of phenomenon can be easily observed in avian such as domestic chickens and ducklings, and it was described as “imprinting” by Konrad Lorenz in 1935 based on his observations of goslings. The word “imprinting” indicates that the learning process of the characteristics of certain objects in young animals is like an inborn and fixed mechanism. Some advanced behavioral and psychological development, such as social bonding and language skills, are believed to have a close relationship with imprinting process.

Imprinting as an Ethology Topic

The concept of imprinting was developed from the observation with animals. Young birds such as ducklings imprint on the first moving object they observe in life; in most cases the object is the duck’s mother. After imprinting, the baby duck walks just after the imprinting object. This remarkable learning

process was first documented by Douglas Spalding, an English biologist, and the process was described as “stamping in” (Spalding 1873). The similar phenomenon was also described by a German biologist Oskar Heinroth in 1911 (mentioned in Bateson 2000), one of the founders of ethology, who used the German term *Prägung* (means “imprinting”) to describe this phenomenon. However, it was Konrad Lorenz (1935), a student of Heinroth, who made the phenomenon of imprinting well-known through a considerable amount of research work. The most famous experiment was that Lorenz showed his own leg to goslings during a particular period after hatching, and the goslings would follow Lorenz rather than their own mother. Lorenz also found that goslings would imprint on inanimate objects (e.g., a box placed on a running model train) if exposed to it during a particular period. This simple but special act of following was thought to be a determination of social bond between the newborn and their parents (Lorenz 1937).

It was further discovered by Lorenz that the age of the birds influenced imprinting (Lorenz 1937). Imprinting would develop naturally and steadily if the object was shown during the first two days after birth. Otherwise, when the object was shown before or after that period, the phenomenon of imprinting would hardly occur. This indicates imprinting only happens during specific periods of development, and the specific period is called critical period or sensitive period. Learning a particular behavior would be easiest during the corresponding critical period.

The finding of imprinting is regarded as one of the most famous studies of ethology (e.g., Krebs and Sjölander 1992). Unlike behaviorists who estimate the responses of animals to specific stimuli which are usually manipulated in laboratory context, ethologists prefer putting much emphasis on animal’s evolutionary adaptivity. They explore the common behavior patterns under natural conditions among different species and believe that existing animal behavioral patterns are generally resulted from evolution. Imprinting is obviously thought of as an adaptive behavior. The function of imprinting is to enable the young animal to recognize and follow the parent instinctively shortly after birth, which will increase the offspring’s

survival probability greatly. Through imprinting the newborn offspring could recognize its parent for protection from the dangerous situation, such as being hunted by enemies or being isolated by other members of the same species. For the parent, imprinting could help them identify their offspring so they would not waste time and energy caring for those who are not their offspring. Thus, the probability of species' successful genetic transmission could be improved greatly through imprinting.

Furthermore, the imprinting developed at the early age also shows long-lasting influence on the offspring's mating behaviors, which is called sexual imprinting. For instance, male zebra finches preferred to mate with those who looked like the female bird that reared them, rather than the birth parent, in the case when they are born and reared separately by different parents (Immelmann 1972). Though sexual preferences may also be influenced by other predictors throughout later developmental experience, sexual imprinting still has a long-lasting and unavoidable impact on sexual choices across species.

Imprinting and Learning

Some researchers pointed out that imprinting was a special type of learning in nature. In order to emphasize that imprinting is distinct from learning, Lorenz (1970) proposed the process of imprinting with four characteristics: (1) it happened during a restricted time interval which was called sensitive period or critical period; (2) the process of imprinting was irreversible; (3) this type of learning may occur long before it could be behaviorally demonstrated; and (4) it consisted of supra-individual and species-specific characteristics. According to Lorenz the two most important characteristics of imprinting are irreversibility (the property that after imprinted by a specific object, the organism would always prefer the object to other stimuli) and the existence of critical period.

Although the claim by Lorenz of the irreversibility and critical period of imprinting has been refuted with experimental evidence in birds (e.g., Hoffman et al. 1972; Salzen and Meyer 1968), the characteristics of imprinting concluded by Lorenz

still have important significance for differentiating imprinting from other types of learning such as associative learning and perceptual learning.

From the perspective of perceptual learning theory, imprinting is the consequence of being exposed to the particular stimulus at early time. In studies of perceptual learning, animals present behavior pattern similar to imprinting. For example, rats performed better in discrimination tasks if exposed to the similar stimulus from birth (Gibson and Walk 1956), which indicated that similar with imprinting, perceptual learning was also related to the familiarity with objects.

Yet, perceptual learning is more like the formation of internal representation of a specific stimulus, rather than a more complex process in which organisms form a behavioral (van Kampen 1996).

Another stream of research has been focused on the similarities and differences between imprinting and associative learning. Associative learning includes classical conditioning and operant conditioning. Some researchers pointed out that some features of an imprinting stimulus acted as unconditioned stimulus (US), which were motivationally significant, and other neutral features acted as conditioned stimulus (CS). This approach hypothesized that birds got attached to shape and color (CSs) of specific object because they detect the relationship between shape or color information with the movement or sound (USs) of the object (e.g., Hoffman and Ratner 1973).

However, with the emergence of more evidence, the claim that imprinting is similar to associative learning was questioned (Bateson 1966; Bolhuis 1991). For example, even if birds' behavior can be reinforced by presentation of the stimulus on which they are imprinted, evidence also showed that birds, which were not able to imprint, could still learn operant tasks (Bateson and Reese 1969). Besides, both classical conditioning and operant learning refer to the formation of associations between neutral and unconditioned stimulus, which can be demonstrated simultaneously or separately, but imprinting seems more like a process through which an animal can detect an object naturally and form a representation of it, rather than predict a specific event. Thus, imprinting helps the young offspring learn to recognize the

characteristics of the parent, while associative learning helps a subject to predict the environment.

In addition, the mechanism of imprinting differs from that of associative learning. In associative learning, predicting the environment involves detecting the order of separate events. But in imprinting, learning to discriminate one object (or characteristic) from another may be the most important task, and the order in which the features occur is not that important (Bateson 1990). In one of Bateson's studies, birds performed better in discrimination tasks if the two objects were demonstrated 5 min or more separately than those in the control group which had not been exposed to the objects. Interestingly, when the two objects were demonstrated 30 s or less separately, the imprinted birds performed poorer than the control group in discriminating the objects. This result can be explained that if presented separately within a short time, different stimuli can be perceived as the properties of the same event, no matter the order of stimuli. In general, there are some similarities between imprinting and associative learning, yet differences also exist in the functions and the mechanisms of them.

Imprinting and the Development of Attachment

Imprinting also provides an alternative explanation of how the attachment pattern is developed.

Based on the characteristics of imprinting, imprinting might be a way to understand the formation of the deep and long-lasting ties between the young and their caregivers. It was concluded by Lorenz (1935) that imprinting served as a specific way for offspring to learn their species' identity, and it lead offspring to form two behavioral patterns: filial bonding and sexual preferences. Attachment, as a motivational and behavioral system (Bowlby 1982), directs the young child to seek proximity with a familiar caregiver and thus is thought to be highly related to the process of imprinting. For example, both of imprinting and attachment take place on the basis of the relationship between the

offspring and the primary caregiver, and both of them focus on the offspring's early experience. Although Bowlby did not include imprinting theory in attachment theory, he also considered that attachment behavior would be best explained as instinctive. These similarities between imprinting and attachment led much literature (e.g., Reed and Leiderman 1983) to discuss whether the development of attachment is a result of imprinting.

Although observational studies of young children in natural settings provided behavioral evidence that might indicate attachment was similar to imprinting, there remained distinct differences between them. For instance, Bowlby's attachment theory included the idea that attachment involved learning from experience during a limited age period, especially influenced by the early social interaction between infants and the primary caregiver after birth, which is different from imprinting (Bowlby 1982). Another example was when staying within a certain distance of the mother without effort on her part and picking up small objects, young children would bring them to the mother but not to others (Anderson 1972). Such kind of behavior may be evidence of attachment, but it may lack the evidence of the essential sensitive period if explained by imprinting. In addition, by studying behaviors of young children, attachment can be described as a developmental process, related to an infant's entire caregiving history, yet imprinting tends to be a learning process that happens in a comparatively shorter period (Reed and Leiderman 1983).

Conclusion

Overall, the concept of imprinting has been developed from the observations of young animals by ethologists. This phenomenon is regarded as an instinct model of early learning which happens within the critical period and is irreversible. Though similar with perceptual learning and associate learning, they are actually different internal mechanisms. Both of imprinting and attachment behaviors emphasize the young organism's

instinctive behavioral pattern; however, they are distinct with each other in nature.

Synonyms

[Impulse-control disorders](#)

Definition

Psychiatric diagnoses that include impulsivity or difficulties with behavioral and/or emotional inhibition as a primary symptom.

Introduction

Impulsivity Disorders refer to the numerous psychiatric disorders that involve impulsivity as a primary aspect of the clinical presentation. Impulsivity may present as an inability to inhibit behavior or emotions, a lack of forethought or planning, and a failure to consider the consequences of one's actions. Examples of impulsivity disorders include pyromania, ADHD, and binge-eating disorder.

Impulsivity Disorders

Impulsivity disorders refer to psychiatric disorders with a primary symptom of impulsivity or deficits in behavioral and/or emotional inhibition. Hollander et al. (2008) define impulsivity as “the failure to resist an impulse, drive, or temptation that is potentially harmful to oneself or other” (p. 778). In summarizing the various definitions of impulsivity, Moeller et al. (2001), focused on the lack of thought, planning, attention, or judgement accompanying behavior. Whiteside and Lynam (2001) identified four personality factors related to impulsivity including urgency, lack of premeditation, lack

of perseverance, and sensation seeking supporting the notion that “In addition to its importance in personality, impulsivity also plays a prominent role in the understanding and diagnosis of various forms of psychopathology” (p. 670).

The DSM-5 (2013) includes numerous disorders that involve impulsivity. The disorders outlined in the DSM-5 (2013) section *Disruptive, Impulse-Control, and Conduct Disorders* involve difficulties controlling behaviors and emotions and “are unique in that these problems are manifested in behaviors that violate the rights of others (e.g., aggression, destruction of property) and/or that bring the individual into significant conflict with societal norms or authority figures” (p. 461). Examples of disorders in this section include intermittent explosive disorder, pyromania, and kleptomania. Intermittent explosive disorder involves distinct episodes of impulsive aggressive outbursts that appear out of proportion to the antecedent event or stimulus and remit spontaneously (Saddock and Saddock 2007). The diagnosis of pyromania includes deliberately setting fires on more than one occasion that is not done for monetary gain, to conceal criminal activity, or as a result of hallucinations or delusional beliefs (American Psychiatric Association 2013). Kleptomania is described as an inability to inhibit the impulse to steal objects that the individual does not need (American Psychiatric Association 2013).

Impulsivity also serves as a prominent symptom in the presentation of Attention-Deficit Hyperactivity Disorder (ADHD). Impulsivity in ADHD can occur within the cognitive, behavioral, and emotional domains. Individual's diagnosed with ADHD to experience impulsive errors due to failing to wait for complete instructions, a lack of understanding of what a situation requires, and failing to consider the consequences of actions prior to initiating behavior (Roberts et al. 2014). Trichotillomania, intentional hair pulling that causes visible hair loss, and compulsive skin picking that causes tissue damage have also been cited as impulse-control disorders (Grant 2008). Other conditions that involve impulsivity include

Bulimia and Binge-eating disorder, substance-use disorders, addictions, Borderline Personality Disorder, Bipolar Disorder, and Paraphilias (Hollander et al. 2008).

Conclusion

Impulsivity involves a lack of forethought, judgment, and behavioral and emotional inhibition. Impulsivity is recognized as a prominent feature of various psychiatric conditions including kleptomania, ADHD, substance-use disorders, and addictions.

[Object permanence in monkeys and apes](#); [Primate object permanence](#)

Definition

Cognitive skills related to the understanding of an unseen object's continued existence in nonhuman primates.

Introduction

Object permanence is the understanding that an object does not cease to exist just because it can no longer be directly perceived. This is a fundamental concept studied in the field of developmental psychology, the subfield of psychology that addresses the development of infants' and children's social and mental capacities. There is not yet scientific consensus on when the understanding of object permanence emerges in human development. Jean Piaget (1952) claimed that children progressively obtain object permanence during the first 2 years of life and that, in its final stages, object permanence extends beyond simply understanding that an unseen object continues to exist to being able to follow the trajectory of an object after its path becomes occluded. Early studies on object permanence were conducted by hiding objects behind screens or in boxes and observing whether infants made a search response and generally supported Piaget's assertion that object permanence is achieved in stages. While some researchers think object permanence is a skill that is gained through innate developmental processes (e.g., Baillargeon 2008), others claim it is a learned skill (e.g., Cohen et al. 2002).

Object Permanence Tasks

Studies examining object permanence in animals have used a combination of visible and invisible tasks. Visible tasks involve moving the search object from to and from hiding locations in the experimenter's open hand or in a transparent "displacer," while invisible tasks involve moving the search object moving to and from hiding locations in an opaque displacer. Both types of tasks may involve either single displacements (i.e., the search object is moved only once and in that hiding location) or double displacements (i.e., the search object is moved first to one hiding location, then from that hiding location to a second hiding location). Single visible displacement tasks provide evidence of whether the subject recognizes that the search object exists even when it is unseen. Double visible displacement tasks provide evidence of whether the subject has the ability to track a visibly moving object. Invisible displacement tasks provide evidence of whether the subject has the ability to track the trajectory of an object once it is out of sight.

Evidence

Tomasello and Call (1997) describe object permanence in nonhuman primates as a type of "physical cognition," which is a term describing the ability to manipulate, categorize, and quantify objects. These complex cognitive skills may be necessary for foraging and extracting food from hidden locations and thereby represent an evolved psychological mechanism (Tomasello and Call 1997). Evidence that object permanence, in particular, is an innate skill is provided by research demonstrating that differences in object permanence between members of the same primate species are small (Call 2000). Object permanence is a cognitive skills shared by a wide variety of primate species. Longitudinal testing of macaque monkeys showed that such skills advance over time providing evidence for an innate mechanism shared between humans and other primates (Hall-Haro et al. 2008). Numerous ape and monkey species have been able to successfully solve

both visible and invisible displacement tasks. However, some highly controlled studies using a series of nine increasingly difficult visible and invisible displacement tasks showed differences between species. Great ape species such as chimpanzees and orangutans have solved all displacements tasks whether visible or invisible and no matter the number of displacements (Barth and Call 2006), while monkey species such as marmosets (Mendes and Huber 2004) and cotton top tamarins (Neiworth et al. 2003) failed invisible displacement tasks.

Conclusion

All primate species have demonstrated some degree of object permanence skills, but those species most closely related to humans demonstrate object permanence abilities that are more comparable to humans.

Definition

Inceptive memory is a representation of the world stored in the way it was encoded at its inception. Derived memory is a higher level of representation that was derived from inceptive memory stores but was computationally transformed to supply in a form that minimizes the need for further processing by the decision rules that use it.

Introduction

It is useful to distinguish inceptive from derived memories as they serve survival. Inceptive memories are representations of external input stored in the way they were encoded at the time at which they were first experienced. Many episodic memories appear to be inceptive; they often contain perceptual detail, proprioceptive information, emotion qualia, a sense of the self as present in the encoding situation, and the sense that the memory is very similar to the original experience. But not all inceptive memories are episodic. It is logically possible to have an inceptive memory about a specific event involving the self without its being episodic in character. It would not be episodic if it lacked the subjective sense of self in space and time that is diagnostic of episodic memory. A derived memory system together with its inferential machinery prepares answers or preprocesses information into usable and ready forms, to facilitate decisions and judgments of a specific type that would otherwise be detrimental if they had to be computed from raw data on demand.

Human Memory and Computation

The computational operations that generate derived memory are not limited to mere extraction of information from inceptive memory. A derived memory can contain information not present in any of the inceptive memories on which it was based, generated by procedures that made inferences from the inceptive data. A derived memory may, in some cases, be the output of the same

decision process that uses it at a later time. For instance, if one needs to decide at Time 1, on the basis of behavioral episodes, whether Person Y is honest, the conclusion might be stored as a derived memory for use at Time 2. A trait summary is a form of derived memory; a stored episode is an inceptive memory. Because of their advantages, human memory may be full of independent, derived memory stores linked to various inceptive memory stores (Nadel 1994). The linked memory stores of abstracted personality traits and behavioral episodes that exemplify those traits may prove to be a model system that can illustrate properties that are common to many memory stores.

Adaptive Function of Memory and Its Properties

The adaptive function of information storage is intrinsically prospective. It is used to support future decisions and judgments, which cannot be known in advance with certainty. To the extent that the character of subsequent decisions and judgments can be predicted, the memory system can be tailored to flag relevant information and precompute variables that are required to make them – that is, it can develop a derived memory store. This set is indefinitely large and hence precluded by limitations on computational and memory resources. In functional terms, factors that should govern the number and type of derived memory stores include (a) predictability, the existence of factors, either ontogenetic or phylogenetic, that allow the successful anticipation of likely varieties of future judgment or decision types; (b) importance, the value of those judgments or decisions ought to justify the costs; (c) urgency, the requirement that such judgments be made quickly; and (d) economy, the number of judgments or decisions supported by a derived memory store should be proportionately large with respect to its size. The use of trait summaries in making decisions about social interactions meets all four criteria.

Benefits and Disadvantages

Storing semantic summaries has both advantages and drawbacks. Direct retrieval of precomputed

representations (derived memory) economizes on online computation and is fast. But it takes up increasing amounts of memory the larger the set of representations that must be precomputed and on tap and may provide information that is no longer up to date. In contrast, procedures triggered online that take inceptive memories as input economize on derived memory and provide up-to-date information. But they are expensive computationally and increasingly slow, the more computational steps that are involved. An architecture designed functionally would be shaped by these trade-offs, using different mixes of memory versus computation for different types of adaptive problem (Pinker 1997, 1999). Decisions about personality traits provide a case in point.

Trait Summaries

Dynamically, when the data set of relevant events is small, judgments about personality traits appear to be made predominantly based on retrieved behavioral episodes (Klein et al. 1997; Klein and Loftus 1990). As the behavioral evidence grows, judgments are increasingly made by accessing an emerging trait summary and decreasingly by accessing relevant episodes. When the amount of experience is high, the semantic summary is well developed, and trait judgments are made by accessing this knowledge (Klein et al. 1997; Klein and Loftus 1990). This process is faster than retrieving and considering individual instances (Klein et al. 1992), and it bypasses and inhibits this other judgment route. Evidence suggests that semantic trait summaries are constructed on the basis of the same set of behavioral episodes that are input into the episodic store (Sherman 1996), although supplementation from other sources of information has not been ruled out. Neurologically impaired individuals who exhibit an inability to retrieve individual events show no apparent impairment in their ability to make accurate trait judgments (Klein et al. 1999) and even maintain the ability to revise their trait judgments based on new episodes they cannot recall. This suggests retrieval of behavioral episodes for trait

judgments lies outside conscious awareness. It further argues that either updating of semantic information occurs as each episode is experienced or else the procedures involved in updating do not require conscious access to the episodic store (Sherman and Klein 1994).

Stored Episodes

Trait summary is valuable in human evolution and survival as it fosters speedy access to information and avoidance of redundant and costly computation. Nevertheless, a summary lacks information present in the episodes from which it was derived. Retrieving a trait summary may be faster than constructing a judgment online from a database of episodes, but it is necessarily less accurate. Maintaining a database of inceptive, episodic memories solves several problems that a trait summary cannot. New information may cause previous episodes to be reinterpreted, drastically changing one's judgments of a person or a situation. Keeping a database of episodes is helpful even when a drastic reinterpretation of previous events is not called for. Judgments can be revised in light of new information.

Conclusion

Memory allows organisms to adjust their behavior on the basis of information they acquire ontogenetically, through their experiences with the world. This connection between personal experience, memory, and behavior implies a close relationship between learning and memory.

Memory evolved to supply useful, timely information to the organism's decision-making systems. Therefore, decision rules, multiple memory systems, and the search engines that link them should have coevolved to mesh in a coadapted, functionally interlocking way.

[Consanguineous sexual relationship](#)

Definition

It is defined as the sexual activity between individuals who are genetically related.

Introduction

Incest is considered a taboo sexual activity. Incest is derived from Latin word *incestus* which means unchaste. It is defined as “any sexual activity between close blood relatives who are forbidden by law to marry” (Kellogg 2005). The Cambridge English Dictionary also defines incest as “sexual activity involving people who are closely related and not legally allowed to marry” (Dictionary 2017). It is a worldwide neglected social issue both in developed and developing countries. As per a recent data from developing countries like India, nearly three out of ten registered cases of rape are due to incest, and it follows an increasing trend (Verma et al. 2017). Considering its rising trend, importance, and impact on the society, WHO classifies it as a silent health emergency (Organization 2004) and is underreported because of social taboo.

Incest: A Journey Through History

Incest is declared as “prohibited degree” of relationship from Biblical period. There is a bidirectional relationship between incest avoidance behavior and taboo. Incest is discouraged and forbidden; hence, people avoid incest, which may give rise to taboo related to incest. On the other hand, because there is taboo associated with incest, people avoid incest (Wolf 2015). Incest carries many social disadvantages (e.g., breach in social harmony, sexual abuse, role-relational confusion, and cultural violation); hence, taboos are created against incest (Wolf 2015). Freudian belief was centered around spontaneous inclination of human to indulge sexually within the family, though it was strongly criticized by many researchers (Wolf 2015). Incestuous characters also appear in mythology in all ancient cultures worldwide (Oosten 2015; Serrano and Gunzburger 1983). These mythological incestuous relationships are depicted in the context of disastrous outcomes, which might have propagated taboo with incest.

Westermarck's hypothesis contradicted the concept given by Sigmund Freud. Westermarck

postulated that children, who grow together in close association, often develop aversion to sexual contact among themselves as they become adult (Morehead 1999). It maintains the integrity of the family and act as a protective barrier against incestuous sexual contacts among siblings.

Incest: Current Status Across the Globe

Incestuous relationship may be consensual or non-consensual. Non-consensual incestuous relationship amounts to rape. Victims of incest may not pursue legal or retributive actions against the family because of fear, helplessness, negative attitude, and stigma toward him or her (Fontes and Plummer 2010; Yildirim et al. 2014).

Incestuous relationship between parent-children and among siblings is prohibited legally as well as socioculturally, worldwide (Holanda Júnior 2017). In England and other Western countries, it is regarded as a cognizable offense. Both men and women, above the consenting age, are punishable according to law, even if there is consent. In India, however, incest per se is not an offense. Police can take cognizance of such cases only when the offense can be charged under Section 376 (rape), 497 (adultery) Indian Penal Code, or under the provisions of POCSO (Protection of Children from Sexual Offences) Act (Modi 2011). In the current society, some incestuous relationships are socially sanctioned in certain regions, which results in consanguineous marriages. Consanguineous marriages are still prevalent in parts of Africa, Asia, and Middle East. Across the globe, approximately 10% of children are born from parents with consanguineous marriage (Maguire et al. 2018). Consanguineous marriages more commonly happen between cousins (Hamamy 2012). Among other types of incestuous relationships, incest between father-daughter is reported to be most common followed by incest between brother-sister, sister-sister, and mother-son (Sariola and Uutela 1996).

Risk Factors for Incest

There are many risk factors that may encourage incestuous behavior. Early evidence support that

overcrowding at home setting might result in breach in family member's personal privacy, which may increase the risk of incest (Weinberg 1955). Incest aversion refers to negative attitude and feelings of an individual toward an incestuous relationship (Antfolk 2014). It has been believed that incest aversion has an important role in self-regulation and prevention of incest (Antfolk 2014). Incest aversion is stronger among the siblings if they are of opposite gender (brother-sister) than if they are of the same gender (sister-sister or brother-brother) (Holanda Júnior 2017). Similarly females are less incestuous than males due to higher incest aversion (Holanda Júnior 2017).

Incestuous relationships between fathers and daughters may be seen in families where fathers used to have a strong authoritative role and the mother is absent or having significant disability as a result of which daughter is playing the role of mother (Herman 1981).

Impact of Incest

Women who had history of incest are more likely to develop poor self-esteem and often have difficulty in close relationships (Herman 1981). Incestual practice between an adult and their child is usually considered a form of child sexual abuse and may lead to development of sexual dysfunction, depression, anxiety disorder, substance abuse, borderline personality disorder, and post-traumatic stress disorder (PTSD) in later part of life. Incestuous relationship results in inbreeding, which has various health hazards because the expression of otherwise recessive alleles, due to homozygous states, might cause development of complex diseases and reduction in longevity (Rudan et al. 2003). Evidences support increased mortality of children born from consanguineous marriages (Rudan et al. 2003). Consanguineous marriage also increases the risk of recurrent pregnancy loss, stillbirths, early death of child, X-linked disorders, autosomal dominant disorders, mental retardation, as well as limb abnormalities (Shawky et al. 2013). The

children born from incest are often at risk of developing rare recessive disorders like homocystinuria, congenital ichthyosis, deaf-mutism, retinitis pigmentosa, glycogen storage disease, cystic fibrosis, and progressive cerebellar degeneration. They are also at high risk of developing congenital organ malformations (Super 1981).

Incestuous relationship during childhood is often a traumatic experience that adversely affects the mental well-being. The cognitive behavioral and other psychotherapeutic interventions for the victims of incestuous abuse focus on understanding the traumatic stress, psychodynamics, concept of self, as well as the relational aspects with the perpetrator (Courtois 1997).

Conclusion

Due to taboo, incest often goes unnoticed and underreported, even though it is equally traumatizing like any other sexual crime. When it is socially sanctioned and resulting from consanguineous marriage, it is important to look for the health of the progeny born from the incestuous relationship.

Incest Avoidance and Dating

Debra Lieberman and Joseph Billingsley
University of Miami, Coral Gables, FL, USA

Introduction

Humans, like many other animals, possess information-processing programs that guide mate choice. Inherent in mate choice programs are procedures that weigh the potential benefits versus costs of selecting a particular individual as a sexual partner. The question is, which attributes would have been causally linked to the probability of reproductive success and thus part of the calculation that assesses the costs versus benefits of a given sexual partner? Furthermore, how are different attributes traded off against one another? After all, one rarely encounters a mate that is a “10” in every desirable category. That is, one is unlikely to encounter (never mind attract and retain) a mate that is a 10 in every relevant category. Instead, individuals vary in their value as a sexual partner, and to the extent that certain trade-offs had greater positive feedback with respect to selection, then we should see psychologies sensitive to making such trade-offs.

The field of evolutionary psychology has identified many attributes that contribute to a man's and woman's value as a sexual partner, including attractiveness, intelligence, and resource status (e.g., Buss 1994). There has been less discussion, however, of how these attributes are traded off

against the other factors that might influence mating and dating. One model of mate choice discussed by Lieberman and colleagues (e.g., Tybur et al. 2013; Lieberman and Patrick 2018; Lieberman et al. 2018) suggests there are four major factors that interact to shape perceptions of sexual desirability: (i) the mate value of a potential sexual partner, (ii) one's own mate value, (iii) the perceived availability of mates in the social environment, and (iv) the estimated genetic relatedness between oneself and a potential sexual partner.

In unpacking the factors highlighted by this model, let's first clear up some terminology and distinguish two key terms: *sexual value* and *mate value*. Sexual value is a term for sexual desirability, but it refers specifically to the desirability of another individual as a sexual partner *for oneself*. In this sense, sexual value is a subjective term. Mate value, by contrast, is more objective; it is an abstract assessment that refers to the sexual desirability of another individual *in general*, not for oneself.

Several observations support the notion that sexual value and mate value are related, but distinct, psychological computations. First, individuals from around the globe show surprising consistency in their ratings of physical attractiveness (Symons 1979). Second, people are capable of assessing the mate value of both men and women. Specifically, men and women can rate both men and women in terms of their physical attractiveness, evaluating members of the same and opposite sex on a single scale ranging from extremely attractive to extremely unattractive. But ratings of physical attractiveness do not equal sexual attractiveness to the rater: A man might know his best friend is physically attractive, for instance, yet find the prospect of having sex with him quite disgusting. Third, we can assess the mate value of our genetic relatives (both same and opposite sex), but typically object to sex with our relatives even when assessing their mate value as high. A brother might know his sister is very good looking (and vice versa) but the fact that they have categorized each other as close genetic relatives means that an otherwise attractive

sexual partner is turned into a sexual partner of last resort. Thus, mate value is not sensitive to genetic relatedness, but sexual value is.

In general, then, two factors that get traded off against one another to generate a person's sexual value are mate value and degree of genetic relatedness. Much as mate value is computed based on cues that in ancestral environments correlated with fertility and the ability to rear offspring, genetic relatedness is computed based on cues that correlated with a person being a close genetic relative in ancestral social environments. Extensive research has examined how humans assess relatedness (for review, see Bressan and Kramer 2015). Such research suggests that different cues help to identify different types of close relatives. For instance, men use cues of partner sexual fidelity to identify potential offspring (Daly and Wilson 1988; Apicella and Marlowe 2004; Billingsley et al. 2018), whereas women likely use cues of birth. Children use cues of shared parental investment to identify potential siblings (Lieberman et al. 2007; Lieberman and Billingsley 2016), and likely use information regarding nursing frequency to determine motherhood. It is not yet known how children identify their father, but one hypothesis is that children track which man invests most in them and their mother to discern a likely father from other male relatives and unrelated men in the social environment.

Whatever the cues may be, a model of kin detection in humans posits a specific type of program that computes a *kinship estimate* based on the cues associated with a particular individual. This estimate of genetic relatedness is then one input for the system that calculates a person's sexual value. For instance, a woman who is evaluating a male might find him to have high mate value, that is, he is healthy and is intelligent, he has resources, and appears willing to invest those resources in a mate. If this male is *not* a relative, this positive mate value could lead to a high and positive sexual value. However, if he is a close genetic relative, like a brother, the elevated kinship estimate counteracts the high mate value, promoting incest avoidance by pushing sexual value very low.

How low? Well, this depends on the other two factors mentioned above: the availability of potential mates and one's own mate value. Plus, it depends on one's own gender, specifically, on how the sexual value system was calibrated during development. The availability of potential mates should moderate the estimated sexual value assigned to a given person. For instance, a person of moderate mate value might be assigned a higher sexual value when there are few potential partners available than when the environment is rich with possible sexual partners. Aside from anecdotal evidence of imprisoned heterosexual men who might engage in homosexual activities in the absence of available females, psychological research suggests mate availability is an important factor in our sexual psychology. As an example, Daniel Conroy-Beam et al. (2016) found that for people in a relationship with a partner of relatively lower mate value, the perceived availability of better partners was linked to lower relationship satisfaction. The context of what's available and perceptions of an individual's mate value are somehow interacting to generate sexual motivations and partner preferences.

As Conroy-Beam's study also suggests, one's own mate value also influences assessments of sexual value. Only individuals who perceived themselves to have higher mate value than their partner experienced the reduction in relationship satisfaction. In another study (Morgan and Kinsley 2014), researchers manipulated how men felt about their own mate value and then had them look at both attractive and unattractive faces. They found that all men in the study looked at the attractive faces and did so regardless of whether they were led to believe they were of high or low mate value. But men who were led to believe they were of high mate value looked less at the unattractive faces as compared to the men led to believe they were of low mate value. These results suggest that the mind takes into account one's own condition when making decisions regarding whom to pursue as a sexual partner.

Despite the fact that both men and women likely weigh similar kinds of information when assessing a person's sexual attractiveness, there are good reasons to expect that male and female

brains show different sensitivities to these pieces of information. Take relatedness as an example. Although there are costs of inbreeding that affect both men and women, women are expected to be much more sensitive to these costs because women have a much higher minimum level of investment in a given offspring as compared to men (Trivers 1972). That is, relative to men, women should find a given event of inbreeding more objectionable because women experience larger opportunity costs when it comes to biologically risky sexual encounters. What this means is that the conditions under which a female might consider having sex with a brother need to be far more dire (e.g., on a deserted island with no available mates at all for decades) as compared to the conditions under which a male might consider having sex with a sister (e.g., on a deserted island with no available mates for a month).

In terms of the psychological programming, female minds might be organized to weigh relatedness quite heavily and negatively and not allow for other inputs to change this easily (e.g., number of mates available and one's own mate value). By contrast, in male minds, sexual value might be more labile, and changed more easily given various contexts. Certainly more work is required to determine the veracity of these claims and how the model proposed above fares in comparison to other proposed models of sexual attraction.

What does all of this have to do with dating? By and large, men and women possess sophisticated programming, calibrated and tuned over the course of one's lifetime, to help guide mating decisions. Our evolved systems are well equipped to prevent us from sexually desiring our genetic relatives and those perceived to be of low mate value. However, under novel cultural conditions, our system might not operate in the manner we typically expect. For instance, it is possible that the natural mechanism for detecting kin and thus for avoiding incest, can be disrupted. One example would be siblings raised on the Kibbutz. If most siblings were reared apart in separate children's houses, then siblings would not have categorized one another as kin to the same extent as they would have had they lived under the same roof more regularly. This holds true for siblings

separated at birth. Another modern phenomenon is sperm-banks. As sperm-banks become more widely used, women who have never met might be giving birth to paternal half siblings. Should they meet, no natural aversion will be present that arose due to the operation of a kin detection system. Like two strangers, should they meet, half siblings will be left to evaluate each other based on the desired characteristics in a potential mate. Although the chances of such an encounter in the US are extremely low, in some places it can be a bit higher. For instance, in Iceland, a country with a population of just under 400,000, there is now an app to help people identify potential relatives. Before they date, Icelanders can now find out if they are cousins.

Conclusions

In conclusion, Darwinian insights into mating psychology can help reveal the factors that generate a sense of sexual attraction and the circumstances in which each factor might weigh heavily or not at all.

Definition

Cortisol is a major steroid hormone in humans that is secreted by the adrenal cortex during the experience of stress as part of an adaptive coping response. Cortisol has wide-ranging effects, largely functioning to alter an organism's immediate response to the stressor, modulate their response to a subsequent stressor, and aid in their adaptation to a chronic stressor.

Introduction

Cortisol is synthesized and secreted by the adrenal cortex following stress-induced activation of the hypothalamic-pituitary-adrenocortical (HPA) axis – the principal endocrine component of the stress response system. During the experience of stress, HPA axis activation causes a neuroendocrine cascade of events that result in the synthesis and secretion of glucocorticoids (GCs) – primarily cortisol in humans and corticosterone in other species. When environments or situations are judged to be harmful, threatening, or challenging (i.e., they are *stressful*), the central nervous system sends signals to the hypothalamus, which then secretes corticotropin-releasing hormone (CRH) to begin the neurobiological sequence of events that results in increased cortisol levels. CRH

signals the pituitary gland to secrete adrenocorticotrophic hormone (ACTH), which is then taken up by receptors in the adrenal glands – a pair of relatively small endocrine glands laying above the kidneys. In turn, the adrenal cortex, which constitutes the outer covering of the adrenal gland, is stimulated to release cortisol.

As a corticosteroid and glucocorticoid, cortisol has diverse effects on physiological functioning, including: increasing blood pressure; increasing blood sugar levels; suppressing the immune system and reducing inflammation; promoting the breakdown of glycogen, lipids, and proteins; and generally, mobilizing the body's energy resources. Compared to the relatively quick response of the sympathetic division of the autonomic nervous system during the experience of stress, the HPA axis mounts a more delayed, long-term response. However, the HPA system does have rapid effects as well, such as fast negative feedback into the HPA circuit, likely mediated by putative membrane steroid receptors (Nesse et al. 2010). Elevation of cortisol generally starts about 5 min following stressor exposure, with a peak between 10 and 30 min. Some of the effects of cortisol begin after an hour and may be observed for several hours or more. HPA activity is regulated by a hierarchy of feedback loops at different levels in the axis (see Gunnar and Vazquez 2006), and the sensitivity of these feedback loops is a major factor in determining HPA responsivity (Del Giudice et al. 2011).

Cost-Benefit Trade-Offs

As with any trait, the cortisol response is associated with cost-benefit trade-offs. While cortisol plays a role in regulating blood pressure, glucose metabolism, and immune function in order to facilitate acute biological responses to stressors, chronic secretion of glucocorticoids has been associated with various forms of pathology and disease. Chronic secretion of GCs has been linked to depression, insulin resistance and diabetes, hypertension and atherosclerosis, bone loss, and

disorders involving decreased immune function (see McEwen 1998). Chronic GC secretion has also been shown to adversely affect the hippocampus – an area of the brain intimately linked to memory and learning – where decreased dendritic branching, loss of neurons, structural change in synaptic terminal, and neuron regeneration inhibition have been noted (see Sapolsky 1996). Despite the substantial costs that are sometimes linked to chronic GC secretion, natural selection has shaped this stress-responsive trait because the associated benefit to organisms is even more significant.

Functions of the Cortisol Response

Cortisol, and more broadly, glucocorticoids (GCs), modify an organism's response to stress in several notable ways that vary as a function of environmental or situational context. In general, cortisol functions to mobilize available resources and serves as a counterbalance to sympathetic activation during the stress response process. Mobilization of resources may include those that are physiological or psychological in nature (see Sapolsky et al. 2000). Functioning as a counter-regulatory mechanism to help counterbalance the effects of sympathetic activation that can result in wear and tear on the body, cortisol can aid the recovery of the organisms as well (see Boyce and Ellis 2005).

What Does the HPA Axis Respond to?

Cortisol plays a pivotal role as mediator of environment adaptation, but significant physiological costs and side effects associated with elevated cortisol responses contribute to the HPA axis selectively responding to specific types of challenges. The HPA axis generally responds with increased cortisol when people (1) encounter unpredictable and/or uncontrollable challenges that require them to be alert and involve an element of anticipation, and (2) when challenges

involve social-evaluation or relational threat (for review, see Dickerson and Kemeny 2004). The body of literature assessing HPA axis responses to stress overwhelmingly demonstrates that activation of the HPA axis and secretion of cortisol is strongly linked to social feedback. The HPA axis is highly responsive to separation and rejection experiences in family life for infants and children, while a similarly strong response is associated with older children in adults in the context of peer evaluation. Social evaluation was likely important in the context of evolutionary history, as negative evaluation carried with it the potential to incur a loss in social status or result in social ostracism, rejection, and loss of social bonds (Del Giudice et al. 2011).

Sex Differences in HPA Axis and Cortisol Response

Sex differences in biological and behavioral responses to stress likely developed during human evolutionary history. Although the basic architecture of the SRS – including the HPA axis – is the same for both sexes, the types of events or environmental contexts that trigger a response in men and women differ (Del Giudice et al. 2011). Generally, men tend to exhibit greater activation of the HPA axis than women during tasks related to achievement. The heightened response in males may be due to achievement-oriented tasks involving a challenge to status, subsequently enhancing the salience. Compared to males, females tend to demonstrate greater responsivity of the HPA axis in situations where social rejection is involved (Stroud et al. 2002). The enhanced salience of rejection experiences in females relative to males may be explained – in part – by Taylor et al. (2000) tend-and-befriend theory of biobehavioral responses to stress. Following this model of sex differences in behavioral and biological responses to stress, men follow a pattern of responsivity that closely follows the sympathetic fight-or-flight response. However, in females, environmental threats or challenges elicit a “tend-and-befriend” pattern of stress responding. This pattern involves caring for and

protecting offspring as a tending response and also involves affiliation with a group and efforts to seek social support as a befriending response. Given the response preference in females for tending and befriending during times of stress, real or imagined rejection experiences would be expected to be highly salient for females, resulting in enhanced activation of the HPA axis and subsequent cortisol secretion.

Conclusion

Cortisol is a major steroid hormone in humans and end product of HPA system activation during the experience of stress, serving as a critical component of adaptive coping. Cortisol has a diverse range of behavioral and physiologic effects, functioning to alter an organism’s immediate response to a given stressor, modulate their response to a subsequent stressor, and facilitate adaptation to chronic stressors. Like all traits, the stress response associated with HPA system activation and increased cortisol is associated with cost-benefit trade-offs. The HPA axis is particularly responsive to unpredictable and/or uncontrollable challenges and social-evaluative threat. While the basic architecture of the HPA system is the same between sexes, differences in biological and behavioral responses to stress likely arose during human evolutionary history as a consequence of different environmental demands on males and females.

Definition

The role of cooking in increasing energy uptake from the diet as well as reducing the body's costs of digestion.

Introduction

Cooking food is a unique human activity spanning across all cultures, and humans appear to be evolutionarily adapted to this crucial aspect of their diet (Wrangham and Conklin-Brittain 2003). The value of cooking lies in its ability to widen the range of foods that are safe to eat (whether by making their digestion easier or neutralizing toxic compounds) as well as extract more energy from the foods ingested. Both human and animal studies illustrate that the more cooked food there is in a diet, the greater the net energy gain for the eater (Carmody and Wrangham 2009), and a diet of raw foods is energetically inadequate even when various nonthermal processing methods are employed (Koebnick et al. 1999). The effect of cooking on the energy gain from eating includes several mechanisms: increasing digestibility and thus caloric value of ingested foods, lowering the body's energetic costs of digesting, and mounting an immune defense against food pathogens.

Cooking: Digestion Costs

Eating requires the body to use energy: ingesting and assimilating a meal leads to an increase in the metabolic expenditure – termed diet-induced thermogenesis or DIT – that accounts for about 10% of the total energy budget for those of us on a Western diet (Westerterp 2004). DIT increases with masticatory effort, thus softer foods that require less chewing lead to lower metabolic expenditures. Cooking is expected to lower DIT by reducing the structural integrity of foods (Carmody and Wrangham 2009), though no mammal studies have tested this hypothesis. Only one study with pythons provides direct support, where a cooked meat diet resulted in a 13% decrease of

Increased Energy/Reduced Digestion

Net energy gain

digestion costs compared to the raw meat version (Boback et al. 2007). Since nonthermal processing methods – such as using tools to pound or grind foods – would also make food less firm (thus facilitating chewing and lowering digestion costs), some suggest that cooking was not a necessary part of ancestral diets as tool use could have increased energetic intake without the need for fire (Cornélio et al. 2016).

Net Energy Gain: Starches

Energy increase from cooked starches is well-known, as heat improves digestibility of such foods in two ways: it causes a collapse of the structures of raw starch granules (termed gelatinization – a process that increases starch degradation in the digestive tract) and it denatures enzyme inhibitors present in the foods leading to better digestion of starches in the human mouth and gut (Svihus et al. 2005).

In order to compare the net energy gain resulting from cooking as opposed to nonthermal processing methods, Carmody et al. (2011) put mice, a model omnivorous mammal, on three versions of a starchy diet – raw, pounded, and cooked sweet potato. A number of studies have already shown that cooking substantially increases digestibility of starchy foods – from 6% to 206% depending on the food item (Carmody and Wrangham 2009). Carmody and colleagues, however, also demonstrate that the effects of cooking specifically exceed the effects of pounding: while mice maintain their weight on the cooked version of the diet, they lose weight on both the raw and pounded versions. In addition, they preferred cooked sweet potatoes the most, after having tasted the raw, pounded, and cooked variations. Since mice were hungry following a fast, the authors suggest that higher preference for the cooked version was partly due to its energetic advantages.

Net Energy Gain: Fats

Cooking also appears to increase caloric gain of dietary lipids: Groopman et al. (2015) show that

for cooked peanuts, lipid digestibility as well as net caloric gain (measured by body mass increases of mice) significantly exceeds that of raw peanuts. In addition, their results indicate that non-thermally processed (blended) peanuts do not lead to increased lipid digestibility or net energy gain. Cooking appears to “predigest” oil bodies (structures where peanuts store their lipids), because heat mimics the disruptive effects of a digestive enzyme peptin on the proteins that protect lipids from digestion.

Net Energy Gain: Meat

The effect of cooking on animal foods has been less clear. On the one hand, some consequences of heat processing should increase meat's energy value, such as heat-induced protein denaturation: as heat unwinds proteins, it increases their susceptibility to protein-digesting enzymes in the small intestine. Other positive effects include compromised structural integrity of cooked meat (heat gelatinizes collagen and makes separation of muscle fibers easier) and deactivation of foodborne microbes (thus, lowering the body's energetic costs of an immune defense). On the other hand, dry heat methods result in caloric loss due to fat dripping, and protein digestibility can be reduced due to the Maillard reaction – chemical reaction during cooking responsible for the appetizing flavors and aromas of cooked foods. These flavors increase meat palatability and attract not only humans but also great apes (e.g., chimpanzees, gorillas) that spontaneously prefer cooked meat samples to raw ones (Wobber et al. 2008). Thus, while the Maillard reaction might decrease protein digestibility in some ways, it may increase the amount of meat eaten due to increased palatability.

Carmody et al. (2011) test cooked and raw meat diets on mice, once again contrasting the effects of cooking with a nonthermal alternative – pounding. Authors predicted weight loss on all three versions – raw, cooked, and pounded – since a 100% meat diet is not expected to be beneficial for an omnivorous species. While mice did lose weight on all three, only cooking (and not pounding) had a positive effect on energy

gain as mice on the cooked version experienced the least body mass loss. Considering that intake on the cooked version was in fact lower than on the pounded diet, the higher energy gain with cooked meat is intriguing. This result can be attributed to decreased effort required for chewing as well as improved digestibility through heat's denaturation of proteins. Denaturation results in unwinding of proteins from their tight structures, making them more susceptible to digestive enzymes in the small intestine. This process increases the proportion of protein digested by the eater in the small intestine, compared to that digested by the gut bacteria in the large intestine – this is important for the animal's net energy gain, because very little energy is returned to the consumer from the microbial fermentation of protein.

Another potentially important mechanism behind the increased energy gain from cooked meat is the decrease in meat pathogens, which lowers the metabolic cost of an immune defense. Such cost can be substantial, as fever alone can increase resting energy expenditure by up to 13% for each degree celsius increase in body temperature.

Carmody and Wrangham (2009) calculate that, without customary cooking, the cost of bacterial infections for a US consumer would be substantial, as one would be expected to fall ill 42 times per year from foodborne bacteria in meat. The annual cost of immune upregulation due to fever would be almost 7 years worth of basal metabolism versus less than 1 day when customary cooking is employed. Thus, incidence of foodborne illness from meat eating is 99.98% lower due to cooking.

The ability of thermal processing to kill pathogens could have played an important role for early hominins, as some scholars propose that scavenging was the main strategy of obtaining meat in our evolutionary past (Smith et al. 2015). Considering that scavenged meat would likely accumulate pathogenic bacteria, it would have been a costly strategy before the adoption of cooking. Smith et al. (2015) examine bacterial loads on meat and bone marrow, demonstrating that open-flame roasting is highly effective at reducing bacteria or entirely eliminating it. Thus, a simple cooking method available to

early humans – roasting over an open flame – would have decreased the risks associated with meat ingestion, facilitating increasing amounts of this high-quality food in the human diet.

Conclusion

Cooking leads to an increased caloric value of foods in several ways: by lowering the body's metabolic cost of digesting through decreased chewing effort; increasing digestibility of foods rich in starches, lipids, and possibly proteins; and reducing the metabolic cost of producing an immune defense against foodborne bacteria. These factors point to cooking as an evolutionarily important behavior, as increases in energy can be expected to have important effects on human evolution (e.g., expansion of the brain due to the rise in the energy value of the diet). This potential significance of cooking in our evolutionary past is challenged by alternative non-thermal processing methods: using tools to pound the foods also reduces their firmness, aiding in digestion. However, work with modern raw foodists, who heavily process their foods without heat, reveals caloric insufficiencies of even such high-quality diets. In addition, animal studies contrasting cooking and nonthermal alternatives show significant net energy increase only with cooking, demonstrating that tool use can not match the effectiveness of heat in increasing energetic intake from eating.

Increased Grandchild Survival

Antti O. Tanskanen^{1,3} and Mirkka Danielsbacka^{1,2}

¹Department of Social Research, University of Turku, Turku, Finland

²Population Research Institute of Finland, Helsinki, Finland

³Population Research Institute of Finland, University of Helsinki, Helsinki, Finland

Synonyms

Grandparental investment; Inclusive fitness

Definition

Child survival is one of the most important fitness indicators in evolutionary studies. In our evolutionary past, grandparents may have increased their inclusive fitness by helping to keep their grandchildren alive.

Introduction

Humans have been often defined as a cooperative breeding species, meaning that other people in addition to the biological mother of the child take part in child-rearing (Hrdy 2009). These “allo-parents” are typically closely related to the child and may include the child’s father, older siblings, aunts, uncles, and grandparents. Previous studies indicate that grandparents have often been highly involved in their grandchildren’s lives in both traditional and historical populations and in contemporary societies (Coall and Hertwig 2010). By investing resources in their grandchildren, grandparents can significantly increase a grandchild’s survival (Sear and Coall 2011).

Empirical Evidence

Sear and Mace (2008) reviewed 45 studies that detected associations between kin presence in the same household or village and child survival. In these studies, child survival was indicated among children of different ages, ranging from infants to adolescents. The populations included in the review were mostly natural fertility and natural mortality societies, meaning that modern medical care and welfare services were lacking. These populations included several different types of livelihoods, for instance, historical agricultural societies and hunter-gatherer communities from different countries and continents, providing a comprehensive view of kin effects on child survival.

Based on the review by Sear and Mace (2008), the presence of a maternal grandmother correlated with increased survival rates among grandchildren in 69% of the studies (9/13) and the presence of paternal grandmothers in 53% of the studies (9/17). The effect of grandfathers seems to

be much lower compared to that of grandmothers. The presence of maternal grandfathers was related to increased survival rates among grandchildren in 17% of the cases (2/12) and the presence of paternal grandfathers in 25% of the cases (3/12). Moreover, the presence of paternal grandfathers was related to decreased survival rates in 25% of the cases (3/12).

Even though grandparents (and maternal grandmothers in particular) can often have a positive impact on a grandchild's survival, the effect may vary between ecological and other conditions. Sometimes, grandparental presence can be associated with a decreased survival probability among grandchildren. For instance, a previous study found that the presence of paternal grandmothers was associated with increased mortality rates among grandchildren (Strassman 2011). This could result from resource competition between grandparents and grandchildren, meaning that when the grandparents are old or their health is substantially deteriorated, they may compete with the grandchildren over limited household resources. Even the presence of maternal grandmothers may not always benefit the grandchildren (Sear 2008).

Conclusion

Empirical evidence from traditional and historical populations indicates that grandparental presence in the same household or village has often, but not always, been related to improved grandchild survival rates. These studies have also indicated that the presence of grandmothers tends to benefit the grandchildren more than the presence of grandfathers, with maternal grandmothers often playing the most important role. Therefore, in traditional and historical populations, grandmothers may have increased their own inclusive fitness by helping to keep their grandchildren alive.

Definition

Increasing longevity consists in the process by which the individuals' length of life has expanded throughout history.

Introduction

According to Blagosklonny (2010), the progress of civilization has enabled a drastic reduction of

the death rate of young people – who died mainly due to epidemics, famine, and physical violence – and hence the increase of lifespan. A century ago, for example, the odds of reaching the 100-year age group were 100 times lower (Blagosklonny 2010). In this context, currently, studies show that there are several factors that can influence longevity, among them highlighted the issues related to heredity, gender, socioeconomic status, nutrition, social support, medical care, personality, and behavioral characteristics (Robine et al. 1997).

Historical Factors

Kaplan et al. (2000) highlight four characteristics, which distinguish human life histories from other primates and mammals: “a exceptionally long lifespan, an extended period of juvenile dependence, support of reproduction by older post-reproductive individuals, and male support of reproduction through the provisioning of females and their offspring” (p. 156). In addition, *Homo sapiens* has developed, over the humanity’s history, a large brain and, as consequence of its complexity, sophisticated psychological features (Kaplan et al. 2000).

The authors expose peculiarities in the human adaptation, such as the successful existence of humans in virtually all of the world’s major habitats; the capacity of eating a very wide variety of food, both plant and animal; the contributions of individuals of different ages and sex; and the contributions of men and women in the process of producing food (Kaplan et al. 2000). Those characteristics lead to the understanding that human adaptation is broad and flexible (Kaplan et al. 2000).

At the same time, the human species adaptation can be understood as narrow and specialized in the sense that it is based on a complex diet, having the individuals used their great intelligent to extract and hunt those foods. The species’ adaptation is also based in a life history with a long and slow development, having the individuals a great commitment to learning and intelligence (Kaplan et al. 2000).

The authors conclude that the course of human life is based on complex processes and in coevolution of psychology, physiology, and behavior (Kaplan et al. 2000).

Kaplan et al. (2000) suggest that language learning and the mastering of the environment, as major psychological milestones, have a close connection with a lot of factors. Among them, it can be emphasized the timing of brain growth; the growth rates during childhood and adolescence; the developmental changes in survivorship; the adulthood’s behavioral, psychological, and physiological changes; the profiles risk with age; and rates of senescence and aging (Kaplan et al. 2000).

On the other hand, Harari (2015) points out that *Homo sapiens* was an insignificant ape and that he didn’t have relevant changes in his physiology and not even in the size and external shape of his brain. Thereby, the author defines cognitive revolution as the process by which *Homo sapiens*, as a result of the occurrence of discrete changes in the internal structure of his brain, achieve the domination of the other species (Harari 2015). The author also suggest that humans are social animals, defining the ability of cooperating socially as the key for our survival and reproduction (Harari 2015).

Genetic Factors

Research projects related to twins, adoption, and other family studies have been important in understanding the influence of genes on longevity (Christensen and Vaupel 1996). Thereby, an association between certain genetic factors and longevity has already been found (Christensen and Vaupel 1996). As an example, there is the genetic factor apolipoprotein E, which, according to Christensen and Vaupel (1996), is the most potent “longevity gene” that has ever been discovered in humans. However, these authors affirm that recent analyses have shown that the variation of this genetic factor only explains 1% of the variation in lifespan. In this context, in relation to genetic influence more broadly, Iachine et al. (2006) allege that several studies with twins have shown

that genetic aspects cause approximately 20–30% of all variation in lifespan.

Environmental Factors

According to Christensen and Vaupel (1996), the environmental factors are highlighted as determinants of longevity. They affirm that the decrease of the use of cigarettes, changes in the diet, and the practice of physical activities can influence the increasing of life expectancy. In addition, it is emphasized that current studies have found that an excessive consumption of alcohol can increase the risk of mortality (Christensen and Vaupel 1996), which shows another factor involved with longevity. Furthermore, Christensen and Vaupel (1996) consider three other environmental factors that may be influencing mortality and hence longevity. In this sense, these aspects refer to socioeconomic status, education, and occupation.

Resistance to Stress

Minois (2000) defines stress as external and internal events that arise for an individual, to which he must respond adaptively. Thus, it is stated that organisms can present low or high levels of resistance to stress, emphasizing that resistance to certain stress tends to increase resistance to other types of stress (Minois 2000). In this way, according to Minois (2000), if an individual has already been subjugated to a stress, he will be more able to deal with others stresses that appear to him.

In this context, as the contact with stress is related to aging, it is considered that resistance to stress and longevity are closely associated as well (Minois 2000). Therefore, Minois (2000) affirms that a range of studies concluded that high levels of resistance to stress entail high longevity. In addition, it is considered that, as exhibition to stress raises the resistance to other stresses, a moderate exposure to stress can be beneficial for increased longevity (Minois 2000). Thereby, it is proposed that the contact with mild

stresses can have advantageous effects for longevity (Minois 2000).

Positivity

Positive affect, according to Pressman and Cohen (2005), can be defined as sentiments which reflect a level of satisfactory connection with the environment. Feelings like happiness, joy, excitement, enthusiasm, contentment, and pleasurable sentiments in general are directly related with the concept of positive affect (Pressman and Cohen 2005). The suggestion that positive affect can bring improvements to people's health has been made over the years.

In this context, Danner et al. (2001) affirm that literature has indicated increasingly that attitudes and states related to positive and negative emotions are associated with health and longevity. Thereby, the authors associate optimism with longer life, exposing other studies which sustain the idea that an optimistic way of life, which insofar results in the emergence of positive sentiments, may also contribute to the increase of longevity (Danner et al. 2001).

The correlation between happiness and longevity was noticed by Pressman and Cohen (2005) while analyzing studies made in several countries. The authors highlighted the indication that happier people seemed to live longer, while lower levels of happiness, or higher levels of sadness, presented a correlation with an increased risk of mortality (Pressman and Cohen 2005). However, Pressman and Cohen (2005) explained that there is no unequivocal indication that positive effects are beneficial for health, which implies the necessity of more sophisticated studies over those issues.

Religion

George et al. (2000) affirm the existence of plenty of evidence which reveals robust connections between religiousness and health. Analyzing several studies, the authors highlight conclusions that

lead to the understanding that religion is directly related to health mostly in a positive way (George et al. 2000). The influence of religion is associated with the reduction of disease and disability and with the perceptions of health, energy, and vitality (George et al. 2000). In addition, the studies which analyze the relation between religion and mortality indicate that religious people tend to live longer (George et al. 2000). In the same context, according to the authors' analyses, religion seems to imply better recovery from a variety of physical illness, and also it seems to be associated with a greater tolerance of pain and higher quality of life (George et al. 2000).

It is also important to highlight that George et al. (2000) conclude that religion seems to influence positively in the prevention of mental illness such as in the prevention of substance abuse.

On the other hand, the authors admit that there are specific subgroups in the population who were harmed by religious involvement, leading to direct and indirect negative effects for health (George et al. 2000). Although, it is important to emphasize that, according to George et al. (2000), the most recurrent pattern is that religion has no effect or has positive effect on human health.

The reasons why religion positively affect health seem to be related with prohibitions against risky behaviors and with the perspective by which body has both a spiritual and material meaning (George et al. 2000). The fact that religious people believe in a meaningful existence may also have relevant results for mental health (George et al. 2000). The social support among religious people who participate in the same organization seems to be also a determinant for the good effects religion has over health, insofar, in those communities, people tend to protect and support each other (George et al. 2000).

Conclusion

For thousands of years, studies about the duration of life have arrested the interest of people (Christensen and Vaupel 1996). However, knowledge about what factors are involved in determining longevity is still scarce – and the little

that is known has been acquired in the last years (Christensen and Vaupel 1996). In this sense, it is important to emphasize that there is a great amount of aspects in the context of longevity increase still waiting to be investigated.

Definition

Social status has many definitions; however, it can be considered analogous to “rank” in social

nonhuman animals, whereby the higher in social status a person is, generally the more resources, mating opportunities, and higher fitness benefits they receive. Cues of human status and dominance are discussed below.

Introduction

What does a big bank CEO have in common with a bank teller working at one of its numerous locations? They are both part of the company hierarchy. Their day-to-day experience at work is likely, however, to be very different because they are on opposite ends of the company hierarchy. The CEO has reached the highest possible status, and therefore also holds vast resources, power, and wealth, over and above all others below them in the company. The bank teller, on the other hand, must take orders from all those situated higher in the company’s hierarchy, and can, if there are no safeguards in place, have their salary docked or suspended, be declined a raise, and even be made redundant without much warning.

Status hierarchies are ubiquitous in both non-human and human animal groups where individuals live in relatively close proximity and are in contact often enough for it to be warranted. These hierarchies likely serve a purpose and may be beneficial for individuals within a group to reduce within group conflict. That is, formation of status hierarchies can be beneficial to all individuals in the group as it means that there are less overt and prolonged aggressive interactions between the same individuals. Once a hierarchy is established, most individuals will likely learn their place, although hierarchies can change with members moving up or down the ranks, for example, if an individual dies or is displaced through external factors.

Advantages of High Status

Nonhuman Animals

Being of high social status brings advantages, such as the ability to manipulate resources or even mating opportunities. These benefits have

been well documented in nonhuman animals. For example, studies of red deer have shown that stags of high status displace those of lower rank in order and are able to occupy food areas which have higher nutritional content (Ceacero et al. 2012). Similar results have been observed in a wide range of other animals, such as American bison, crayfish, and willow tits (see Ceacero et al. 2012, for brief review). Thus, being of high status in many animals leads to benefits including the ability to monopolize resources.

Another potential benefit of being high in status is having higher reproductive success or leaving more descendants. While this may in part be linked with the ability to monopolize resources, it is worth discussing as there is a large literature on the subject. In nonhuman primates, for example, the rank a male occupied within the group was positively correlated with reproductive success (Cowlshaw and Dunbar 1991). That is, higher ranked males were more likely to have more mating opportunities and produce more offspring than those which were ranked lower. In a very large study which compiled the research of over 700 published research articles, Ellis (1995) found similar results in a wide range of disparate nonhuman animal groups including rodents, birds, fish, and primates. More recent research has demonstrated many more examples of this link between rank and reproductive success (for example, in Macaques, Schülke et al. 2010). Thus, a major benefit of being a leader in animal societies appears to be higher reproductive success.

Humans

The benefits of high social status or rank are not exclusive to nonhuman animals. High status humans, specifically men, are also likely to increase their reproductive success relative to low status men. Indeed, Hopcroft (2006) presents a comprehensive table of preindustrial cultures in which high status has been positively correlated with higher reproductive success, judged by number of surviving offspring. Other than reproductive success, high status individuals, such as the bank CEO mentioned above, have also been found to have increased economic/resource gains (Cheng et al. 2013). High status individuals gain

not only power but also resources and more mating opportunities, which may then equate to higher reproductive success.

Indicators of Status and Dominance in Nonhuman Animals

Being of high status is important as it can lead individuals to enjoy many of the benefits described above and in nonhuman animals, there is much research linking physical traits with status.

There are many indicators of high and low status in nonhuman animals and these vary based on the species in question. For example, body size and age are indicators of status in some species where larger individuals tend to be the dominant ones (Post 1992). In addition, many animals have secondary sexual characteristics and/or weaponry which can be used as indicators of status or rank, especially in an agonistic setting. Well-known examples include antlers, and caribou and red deer with larger antlers have been shown to be more dominant than those with smaller antlers (Appleby 1982). This research suggests that age, size, and size of ornamentation are all ways in which certain nonhuman animals signal their rank to conspecifics.

Achieving Status in Humans

When looking at humans, in contrast to some of the marked differences between the sexes in some nonhuman animals, it is striking how similar men and women are to each other. That is, one sex does not have prominent weaponry such as antlers or extensively bright coloration which can be used to assert rank/authority. There *are* differences in physical strength, with men generally being stronger (Lassek and Gaulin 2009), and height, with men on average being taller. However, these differences are not as prominent as in many other species, and the examples discussed in the section above. So, how do humans generally reach a position of high status? In many groups, individuals are a part of in everyday life, be it during work, sports teams, or other group-based activities, how do they climb the social ladder?

Recent research suggests that there are two main ways of attaining high status in humans,

dominance and *prestige* (Henrich and Gil-White 2001). Gaining status through dominance usually entails the use of coercion, aggression, or force in order to “make” others follow an individual. Conversely, gaining status through prestige does not require an individual to make others follow them and their orders, but rather intrinsic skills, qualities, and knowledge that they possess motivate others to follow them. The key difference is that while dominant individuals act upon others in order to receive followership, prestigious individuals freely, and somewhat passively, receive followership simply through the characteristics they are perceived to possess.

Examples of the use of two methods of status attainment can be seen in real-world individuals. Billionaire businessman and current US president Donald Trump can be considered a dominant individual. He recently completed building the “Trump International Golf Links” near Aberdeen, Scotland. Even though there was a public attempt to boycott the project, mostly due to the golf course being located on a site of scientific importance, Trump continued with the project. Additionally, Trump continues to fight plans to build a large wind farm close to the golf course claiming that it would spoil players’ views. There is even speculation that Trump has used the law to remove local residents from their homes so that they are not located near his golf course and its adjacent hotels. If these claims are true, then Donald Trump has demonstrated himself to be a forceful, coercive, and dominant individual, achieving his goals despite resistance from others. Even within his presidential campaign/term, Trump has publically berated and been hostile toward candidates, foreign dignitaries, news outlets, people who disagree with him, women, immigrants, and people of different races/ethnicities (see @realDonaldTrump on twitter.com (www.twitter.com) for examples).

In contrast, a real-world example of an individual who might be considered prestigious is the current Dalai Lama. He has championed nonviolence in order to solve conflict, and thus seems unlikely to resort to force in order to get his way. He is also a part of the Elijah Interfaith Institute,

which aspires to open dialogue with many different faiths in order to foster peaceful relations among them with the aim to lead to trust and transparency – in effect the opposite of coerciveness and manipulation. Finally, he has accrued international acclaim and praise, including winning the Nobel peace prize in 1989. It is the Dalai Lama’s many personal characteristics, convictions, and qualities which have led others to hold him very high regard, and he is almost universally acknowledged as an individual who deserves to be listened to and followed.

The stark contrast between Donald Trump and the Dalai Lama is quite evident. While both are high status individuals, holding power and influence over others, the tactics used to achieve this status are very different. While Donald Trump has, in effect, exerted his dominance in order to achieve his goals, regardless of the consequences and who it might affect, the Dalai Lama has earned his status through cooperation, and the many merits and qualities which he shows to those around him.

Recent research has also pointed to social and physical dominance being two different methods of attaining “dominance,” with physical dominance dealing with physical characteristics (such as being able to “win a fistfight”), while social dominance implying more guile (is influential but also tells others what they want; e.g., Puts et al. 2006).

Definitions of Dominance

As the above section implies, there appear to be many ways in which researchers study high status, with some opting to provide definitions while other researchers opt to simply allow participants to use their “gut instinct” to decide what dominance, prestige, power, status, etc., are.

The use or lack of use of a definition can complicate matters, as some researchers divide dominance into physical dominance and social dominance and find differences between the two. For example, studies have found that faces of women which have been manipulated to look more feminine are rated as more

socially dominant, while both women and men's faces manipulated to look more masculine are rated as more physically dominant (Watkins et al. 2012). The definitions used to describe physical and social dominance in these studies were taken from Puts et al. (2006), where participants rated voices for dominance and where physical dominance was described as the ability to win a "fistfight," while social dominance was described as being a respected "leader." This definition of social dominance which also includes words like "influential" was originally used by Mazur et al. (1994) to denote dominance; however, in the context of the dominance and prestige literature mentioned above, where dominant people may not necessarily be respected, this social dominance definition appears to align closer with prestige (Henrich and Gil-White 2001). How exactly social and physical dominance relate to the concepts of prestige and how they relate to, or are potentially subsumed by the concepts of dominance, have yet to be established.

"Status" itself has been used to refer to "an individual [who] is respected, admired, and highly regarded by others" in a recent study (Fragale et al. 2011, pp. 767). This quality was compared with individuals who were powerful, where power described someone who "can control others' outcomes by granting or withholding valued resources" (Fragale et al. 2011, pp. 767). Again the definitions used to describe status and power are similar to those used to describe prestige and dominance, respectively, by Henrich and Gil-White (2001).

It is important to note that the research and studies described below may all have slightly different definitions of dominance and its variants, or prestige, whereby the researchers may either have provided various definitions or allowed participants to use their own internal concepts of human social status to guide their judgments. Moreover, future studies should try to elucidate exactly what individuals are imagining when they are asked about these concepts – for example, what adjectives/characteristics/features would they attribute to a dominant person or a prestigious one?

Overview of Indicators and Correlates to Status in Humans

Many different cues and correlates to social status have been explored in humans within the last 30 years. A few studies pertaining to certain indicators are described below.

Faces

Faces are usually the first thing an individual sees or is drawn to when they enter into an interaction with another person. Faces hold a variety of cues, people use faces to judge people's attractiveness, their trustworthiness, and even their competence (see Todorov et al. 2015 for review), among many other traits.

Dominance has been linked to certain facial characteristics by some researchers, including such as prominent brows, muscular and well-defined jaws, broader faces, and masculinity in men (Mazur et al. 1994). In women, those with more masculine faces are considered as more physically dominant while as those with more feminine faces are considered to be socially dominant (Quist et al. 2011).

Additionally, recent research has shown that facial width-to-height ratio (fWHR) (or the distance between the two zygions with respect to the distance between the lower brow and upper lip) is also related to both self-perceived and other-perceived dominance in men though not to prestige (Mileva et al. 2014). Using self and other report measures, in three studies, the authors found that men with higher fWHR ratios were rated as higher in dominance, and rate themselves as higher in dominance using two different dominance scales. fWHR has also been linked to other behavioral characteristics associated with dominance, such as aggression, where Carré and McCormick (2008) showed, when looking at National Hockey League (NHL) players and varsity hockey players, that those players with higher fWHRs were also more likely to have had longer stints in the penalty box – where players are sent if they have performed an act which is deemed reckless or prohibited in the sport. While some researchers have disagreed that fWHR is linked with aggression, a recent meta-analysis suggests

that the two are positively correlated (Haselhuhn et al. 2015).

Another aspect of dominance which fWHR has been related to is exploitative behavior. Stirrat and Perrett (2010) allowed participants to play a trust game and found that men with higher fWHR were more likely to exploit the trust of those they were playing with than men with lower fWHR. Similarly, Haselhuhn and Wong (2012) found that men with higher fWHR were more deceptive in a negotiation task related to the fictitious purchasing of property, and more willing to cheat in a “dice roll” than men with lower fWHR. As such, at least in men, fWHR appears to be related to dominance characteristics as well as to self- and other-perceived dominance.

The facial features discussed above are static and do not, for the most part, change on a person’s face once they have reached the end of puberty. That is, one cannot easily alter (other than with some types of reconstructive surgery or perhaps through gaining a large amount of weight) one’s facial structure as it delineates the underlying skeletal structure. Facial expressions, on the other hand, are easy to alter and have been shown to interact with dominance attributions. For example, research suggests that men with neutral, angry, and happy expressions are more likely to be perceived as dominant than those expressing fear and sad expressions (Hareli et al. 2009). In women, the pattern is more complex, with some studies suggesting women exhibiting anger expressions are perceived as more dominant (Hareli et al. 2009).

Faces therefore allow individuals to make many attributions about a person, and can also be used to infer their dominance, or perhaps lack of dominance.

Voices

Just as faces are important in signaling dominance during first introductions with a stranger, another important cue individuals can use to gain information about someone’s dominance is that person’s voice. Studies suggest that voices are able to signal dominance, with lower pitched voices being considered as higher in dominance (Puts et al. 2007), especially with respect to physical

dominance versus social dominance. As men tend to have lower pitched voices than women, and men are physically stronger (Lassek and Gaulin 2009), it may not be surprising that dominance is associated with a lower voice pitch. Indeed, masculinized voices (i.e., those with lower fundamental frequencies – equated to pitch) tend to be considered as more attractive by women in general, with the authors suggesting this is due in part to relating to their sexual maturity (Feinberg et al. 2005).

More recent research has again showed that artificially masculinized voices are associated with higher dominance, and are also considered more attractive for short-term relationships rather than long-term relationships by women (Vukovic et al. 2011). This research suggests that voices can be used as valuable cues to someone’s dominance which can in turn impact attractiveness and other judgements.

Height

Another characteristic commonly associated with influential, powerful, and dominant people is height. Indeed, studies asking preschoolers to rate the dominance of men and women of various heights show that height is positively related to other perceptions of dominance (Montepare 1995). That is, tall men and women were considered more dominant than their shorter counterparts.

High dominance would be expected to lead to influence and success, and recent studies have looked at the relationship between height and leadership. In a task where the researchers had participants simply draw a “leader” and a “citizen” using a pen and paper, significantly more participants drew the leaders as taller than the citizens (Murray and Schmitz 2011). In a second study, Murray and Schmitz (2011) also found, through self-report measures, that participants who were taller also thought that they would be more qualified to be candidates for leadership roles than participants who were shorter. In a study examining all previous presidents of the US dating back to 1790, Stulp et al. (2013) showed that presidents were significantly more likely to be taller than other men in their birth

cohort, and that taller presidents were more likely to be reelected, win popular votes, and be considered as better leaders.

Height is therefore an important characteristic, at least for men, in that it can make them appear higher in dominance and consequently higher in leadership characteristics than men who are shorter. In addition, as tall men also rate *themselves* as more dominant and as having greater leadership qualities, this may mean that they are internalizing other's opinions of them and behaving accordingly. Another possibility is that differences in height, perhaps related to differences in circulating testosterone levels, lead to subsequent behavior change (e.g., tall individuals are more likely to exhibit dominant behaviors), which in turn affect other's perceptions. Which and to what degree each of these affects the relationship between dominance and height is not yet known.

Nonverbal Behavior, Personality, and Hormones

Several recent studies have looked at dominance with respect to nonverbal behavior and personality. Cheng et al. (2010) looked at self- and other-rated perceptions of prestige and dominance in a set of undergraduate students as well as male university athletes. They found that high dominance was positively correlated to personality characteristics including extraversion, aggression, and narcissism, and was negatively correlated with agreeableness. In contrast, prestige was positively correlated with extraversion, agreeableness, conscientiousness, self-esteem, and openness, while being negatively correlated with aggression. These results were most evident in the self-ratings of undergraduate students, and provide an interesting insight into the differences between dominance and prestige as separate strategies for gaining high status. Other nonverbal cues related to "aggressive" dominance include a decreased tendency to laugh along with others in a group setting, as well as increased time spent looking around the room as opposed to at others within the group – what the authors consider an attitude of disinterest (Kalma et al. 1993). Additionally, dominant individuals are more likely to have persistent, direct eye gaze, while those who

are lower in dominance are more likely to look away and give only furtive glances at the dominant individual (Mazur et al. 1980).

Color

Bright coloration has been found to be a dominance cue in several animal species including, for example, in face of mandrills (Setchell and Wickings 2006). More recently red has been associated with dominance in humans as well. In a unique study, Hill and Barton (2005) found, when analyzing four different contact sports (i.e., Judo, boxing, etc.) during the 2004 Olympic games, that those contestants who were assigned the color red were more likely to win, and that if there was less ability asymmetry between that individual and their opponent (i.e., where individuals had similar competitive abilities), those wearing red were even more likely to win. Indeed, in a simple study using only shapes of different colors, Little and Hill (2007) found that participants chose red-colored circles or triangles more often than blue when asked which would be more aggressive. Additionally, they found that women were more likely to rate red stimuli as higher in dominance, while men were more likely to rate red stimuli as the "winner" of a contest.

Recent research has shown that men whose pictures have been superimposed onto a red background are more likely to be rated as higher in attractiveness than those posing on blue or achromatic backgrounds, and that this effect is mediated by perceptions of status (Elliot et al. 2010). That is, red is associated with high status, and that leads to higher attractiveness ratings for men on red backgrounds. As such it appears that color can affect attributions of status, dominance, and competitive ability, not only in nonhuman animals but also in humans. Specifically, the color red seems to be linked to dominance, though there may be other colors which have yet to be studied which also appear dominant.

Wealth and Displays of Wealth

Wealth has long been associated with social status and cues to wealth may then be important in

inferring status. Research has focused on the association between wealth and attractiveness. At least in men there are reproductive benefits to being wealthy, with wealthier men having more offspring than less wealthy men both in Western industrialized and more traditional societies (Pérusse 1993). Of course, cues to wealth will be culturally dependent, with specific cues perhaps only being valued in particular cultures. For example, the Mukogodo of Kenya value ownership of livestock but this may not indicate high status to city living New Yorkers, who may look to other cues such as the expense of clothing and items such as watches, jewelry, and cars. Research in Western countries has revealed that manipulations of job titles or clothing linked to wealth is related to attractiveness, at least for men, with professional high-earning jobs making men more attractive to women than lower earning jobs (Townsend and Levy 1990).

Relative Dominance

Research is now emerging on the importance of relative dominance, and while not an indicator of dominance, it is nevertheless worth mentioning. To illustrate, imagine that an individual were approached, somewhat menacingly, by a formidable player in the NFL (or Rugby Union for British readers). In most instances, that individual might respond by being frightened, perhaps for their life, and adopting the decision to run away from the confrontation. However, if that individual is similarly tall, muscular, and menacing, then they might “hold their ground” and opt to continue with the confrontation. This scenario illustrates how important it is to use oneself as a relative marker with which to make comparisons regarding others in terms of dominance.

Recent research in evolutionary psychology has shown that these relativities extend beyond dominance. In one study, women who were not using oral contraceptives and rated themselves as highly physically attractive also preferred men with higher facial masculinity and symmetry, two traits commonly associated with higher genetic quality, than women who thought

themselves less attractive (Little et al. 2001). Thus, relative ratings of attractiveness appear to influence women’s judgments of attractiveness in partners; those who think more highly of themselves, in this case with regard to attractiveness, also believe that they are able to attract and attain a higher quality male, in this case one who is more masculine.

There is relatively little literature regarding relative dominance; however, research by Watkins et al. (2010b) has found that men who rate themselves as high in dominance using a standardized dominance questionnaire are also less likely to attribute dominance to masculinized versions of a face (i.e., they were less sensitive to masculinity when deciding which of two facial images – one manipulated to look low in masculinity and one manipulated to look high in masculinity – was the more masculine one). Taller men have also been shown to be less sensitive to cues of other men’s dominance (Watkins et al. 2010a), and above it was discussed that taller men are also rated by others as higher in dominance. In women, Watkins et al. (2012) showed that those women who rated themselves as higher in dominance and those who were taller tended to be less sensitive to masculinity/femininity manipulations of female faces. These studies suggest that self-perceptions of one’s own dominance can affect attributions of others dominance as well, with those individuals who perceive themselves as being higher in dominance also being less sensitive to cues of dominance from other individuals. Thus, it seems that others’ dominance cues are particularly important to individuals who perceive themselves as being low in dominance, perhaps because they have the most to lose when interacting with a dominant individual (specifically in confrontational scenarios).

These studies indicate that self-perceived and relative dominance are important to address in order to fully explore and understand the nuances of human dominance and dominance perceptions.

Summary

Social status and particularly dominance has been the topic of a great deal of research in the last

30 years. Those who possess high status can earn great rewards (i.e., reproductive success) and as such it is important to know more about the indicators and cues of social status, some of which are briefly touched upon above. However, definitions within the literature differ and it is important to keep this in mind when performing research on social status. In addition, the importance of relative dominance and relative social status is only now becoming elucidated and will no doubt become an important topic of research in the coming years, if for no other reason than to control for individual differences found in research results. In the following sections, some of the above sections and others will be discussed in greater detail.

[Relational aggression](#); [Social aggression](#)

Definition

Indirect aggression is a behavior intended to harm others, particularly others' social position and self-esteem, through circuitous means. It is a kind of social manipulation, in which the aggressor manipulates other individuals or the social structure to psychologically harm the victim, without the direct confrontation. The related constructs of social and relational aggression also represent the same phenomena in which social community or peer group serves a mediating role between the aggressor and victim. Indirect aggression is exemplified by behaviors such as gossiping behind back, spreading rumors, social exclusion, slanderous remarks, etc.

Introduction

Undoubtedly, aggressive behavior is problematic and a potential formative factor in adjustment problems for both aggressor and victim. Initial research has quite commonly focused on male-oriented models of physical aggression. However, it is clear that the aggressor may sabotage their peers in more subtle ways without being disclosed as an aggressor. By using indirect aggression, the aggressor usually remains unidentified and is at low risk of retaliation and thus avoids counterattack. Although researchers have started considering less direct forms of aggression in the latter half of the twentieth century, they have taken serious interest in indirect aggression since the last decade of the twentieth

century (e.g., Crick and Grotpeter 1995). The validity and existence of indirect aggression is also supported by factor analytical studies representing two factors of aggression: first, overt, direct, or physical aggression and, second, covert, indirect, or social aggression (e.g., Crick and Grotpeter 1995).

Regarding socio-environmental correlates, the literature indicates that indirect aggression has been linked with harsh discipline and a lack of positive and supportive parenting during early childhood years (e.g., Park et al. 2005). Moreover, the aggressors using indirect means of aggression show certain cognitive biases such as attributing hostile intentions and a lack of empathy (e.g., Crick et al. 2002). Interestingly, these aggressors as opposed to those who use physical aggression often show superior language skills. They are better at predicting other's thoughts and actions as well as at persuading and manipulating others by using their advanced cognitive and language skills (e.g., Bonica et al. 2003).

With regard to consequences, the indirectly offending behaviors may elicit the same intensity of pain, psychological harm, or distress at least in the victim as physical aggression may elicit. Evidence shows that indirect and social aggression leaves a range of potentially negative and long-lasting effects on the victim (e.g., Owens et al. 2000). Specifically, the literature describes that indirect aggression is often associated with psychological problems coming under the rubric of internalizing problems. A meta-analysis report shows that indirect aggression is more strongly associated with internalizing problems, but physical aggression is more strongly associated with externalizing problems. Interestingly, these differential associations do not differ across gender (e.g., Card et al. 2008). However, on the part of the aggressor, the use of relational aggression is generally not associated with social adjustment problems. Maybe because of social manipulation, these children become successful in forming very close but maybe short-lived friendships. Also, though some of their peers may not like them, they often hold some dominant position in the group (Johnson and Foster 2005).

Developmental Perspective of Indirect Aggression

The literature describes the validity and psychological consequences of indirect aggression; however, most of the supporting data comes from cross-sectional research with little research focusing on the developmental associations of indirect aggression with environmental correlates and psychological difficulties. From few available longitudinal studies based on children samples, it has been found that expression of physical aggression reduces, but social aggression increases from early childhood onward (Côté et al. 2006). Also, social aggression increases over time in children who are physically aggressive, whereas, the reverse has not been supported. Accordingly, Bjoerkqvist et al. (1992) have presented a developmental model of aggression in children. The model describes that during early childhood years, children express their aggression primarily through physical means because they have not yet developed other expressive tools such as social, verbal, and cognitive skills. As the children develop verbal and communicative skills, they start using verbal aggression, and at around 4–5 years of age, they start using social aggression. In the subsequent stage, relational aggression becomes the primary technique of aggression because it has less risk of being disclosed and ultimately less risk of retaliation (Bjoerkqvist et al. 1992). Genetic studies also support this developmental model by describing that both forms of aggression have common roots and share the same genetic factors (e.g., Brendgen et al. 2005) but show different developmental trends, which may be due to other related factors of cognitive and language skills.

Gender Differences in Indirect Aggression

A diversity of studies in the psychology of aggression has approached the question of gender differences. Two major gender differences in

aggression have been observed and reported in the literatures: (i) higher levels of physical aggression in boys and (ii) higher levels of relational aggression in girls. With regard to indirect aggression, it has been reported that these aggressive acts are not commonly reported in boys. Other studies have reported that frequent use of indirect aggressive techniques is found in girls (Crick et al. 1997). Contrarily, a few studies report negligible gender differences in relational aggression. Accordingly, a meta-analysis review based on 148 studies have reported that boys are consistently reported to be more physically aggressive than girls, but gender differences with regard to relational aggression are minimal and trivial though somewhat significant. These patterns of relational aggression are similar across different age and ethnic groups (Card et al. 2008).

Therefore, it appears that during childhood, children may use both forms of aggression but when they grow, they are inclined to use indirect and circuitous means of aggression to attack their victims with minimal gender differences somewhat favoring girls.

Conclusion

In short, validity studies have confirmed two forms of aggression, that are, direct and indirect aggression. Regarding correlates, indirect aggression is related to harsh parenting and cognitive biases on one hand but advanced cognitive and verbal skills on the other hand. Also, it is generally unrelated to social adjustment problems but related to psychological problems of depression, anxiety, and other internalizing problems. The developmental perspective explains that during preschool years, children use physical forms of aggression, but as their language and cognitive skills develop, they start using indirect and social aggression. Finally, it has been discussed that gender differences are clear regarding physical aggression being more common in boys but minimal regarding indirect aggression being slightly more frequent in girls.

Indirect Benefits of Altruism

Daniel Farrelly
University of Worcester, Worcester, UK

Synonyms

[Cooperation](#); [Indirect reciprocity](#); [Reputation](#)

Definition

The different benefits gained by altruists that are received from individuals other than the original recipients of the act.

Introduction

Traditionally, two theories have mainly been used to explain how altruistic behaviors between organisms can be adaptive, and these are kin selection theory where individuals aid those with which they share a number of genes (Hamilton 1964) and reciprocal altruism where individuals aid others who can and will return the favor in the future (Trivers 1971). These have been mostly adequate in explaining a vast amount of altruism, particularly in nonhuman animals. However, when it comes to humans, there exist a number of examples of altruistic behaviors that neither genetic relatedness or reciprocity can explain. These include giving to various charities (e.g., overseas causes, animal sanctuaries), donating blood or bone marrow, and risking personal

safety to save others (e.g., rescuing a puppy from a burning building). As such examples are not unusual, this contribution will explore how such altruistic acts can still be adaptive in terms of increased survival and/or reproductive success, by showing how their costs are balanced by other benefits that the altruist receives.

Multi-Level Selection

A previous attempt to explain altruism was that it was somehow beneficial for the group, a theory that was all but abandoned in the latter half of the twentieth century. However, a more recent theory of how altruism could have evolved to indirectly benefit groups has been put forward, named multi-selection (e.g., Wilson and Sober 1994; Wilson 2015). According to multi-level selection, natural selection can act on not only an individual but also on a group level. More specifically, even though altruistic members within a group can be outcompeted by selfish members, if the overall fitness of the group is increased by having altruistic group members, then this will be selected for. This can occur in particular circumstances, and the concept of what constitutes a group can vary between levels of organization.

Indirect Reciprocity

This builds on the original suggestion of Trivers (1971) that reciprocity is the benefit an altruist receives. However, whereas reciprocal altruism concentrates on the recipient of the act returning the favor, indirect reciprocity (Alexander 1987; Nowak and Sigmund 2005) states that another individual or third party will return the act to the altruist. This process can work when altruistic acts are reliably and widely broadcast to others in a group, so is highly possible in a social species such as humans who live in groups. As such, a number of contemporary theories have been put forward that show how indirect reciprocity can work and also what specific benefits it provides to the altruist, which are discussed below.

Image Scoring

Image scoring (Nowak and Sigmund 1998) attempts to explain the mechanism by which indirect reciprocity can evolve. Using a theoretical model, they suggest that every individual in a group has an “image score” that relates to their previous altruistic interactions with other members of a group. This is based on group members interacting repeatedly with different individuals in the group in pairs for one-off interactions (i.e., without interacting with that individual again) where one member of the dyad can choose to help the other individual or not. If they choose to help, they have a score of one added to the image score, but if they choose not to help they have a score of one subtracted from their image score.

Therefore, being altruistic in these interactions can increase an individual’s image score which can be beneficial in future interactions. This is because, according to Nowak and Sigmund, individuals in the new dyads will base decision on whether or not to help their new partner on their own “threshold” for image scores. In other words, each individual will have a personal numerical value of image score that a partner must have or exceed for them to decide to help. Any partner in an interaction who has an image score below this threshold will therefore not be helped. So, as receiving help from others can be beneficial, a higher image score is adaptive as it means an individual is more likely to pass a new partner’s threshold and thus provide help. Therefore, this theoretical model provided by Nowak and Sigmund (1998) can show how indirect reciprocity can evolve in groups such as humans.

Competitive Altruism

Competitive altruism (Roberts 1998) similarly uses a theoretical model of how indirect reciprocity can evolve. He suggests that cooperation among group members is a two-stage process, with an “assessment” stage followed by a “partnered” stage. The partnered stage involves

individuals in a group forming long-lasting partnerships where they engage in repeated cooperative interactions with each other. Therefore, as Roberts (1998) suggests, it is important to ensure that a cooperative partner is gained in this second stage.

Furthermore, Roberts suggests that there is an active choice of partners for this second stage (i.e., individuals are able to choose who they have as their partners). As a result of this, individuals will compete with one another to increase their displays of altruism in the assessment stage so that they are a desirable partner. According to Roberts, this then leads to assortative matching whereby the most cooperative individuals will pair together, followed by the next most cooperative, and so on. If altruism in the assessment stage is an honest signal of altruism, then the most cooperative pairs will benefit the most in the partnered stage through their future interactions.

Although the original theory is based on hypothetical models, additional empirical research has shown that humans do indeed follow the principles of competitive altruism when available. In a study where participants first interacted with one another in a cooperative group game (i.e., an assessment stage), those that had behaved most cooperatively in the game were more desired as partners in a further stage where participants cooperated in pairs, and actually benefited more overall (Sylwester and Roberts 2010).

Altruistic Punishment

The idea of altruistic punishment (Fehr and Gächter 2002) is that individuals within a group will cooperate with other group members, as non-cooperation is punished by other group members. This punishment would be severe to act as a deterrent, but will also be costly to perform (i.e., certain group members will incur the costs of punishing non-cooperators even if they themselves do not benefit). Fehr and Gächter show this empirically in a study using the public goods game, where participants can contribute to a public good so that all group members can benefit. However, as often happens in continuous rounds

of this game, individuals stop contributing to the public fund but still get the benefit from those that do contribute. Fehr and Gächter (2002), however, introduced between rounds the opportunity for group members to punish those that had not contributed and found that this was a deterrent that led to those punished individuals to return to contributing, thus ensuring in future rounds that cooperation to the public fund was maintained.

This was found even though it was costly to punish others (although the cost of punishing was less than the cost of being punished), meaning that punishers were behaving altruistic. So what is the motivation to punish, when it is costly and you do not directly interact again with the individual you punished? Fehr and Gächter state a proximate explanation for this, in that we feel strong negative emotions of anger when exposed to non-cooperation (i.e., cheating). Furthermore, the potential costs of punishing may be quite low if minimal punishment is needed to ensure individuals continue cooperating within a group (i.e., potential non-cooperators are aware of the costs they could incur). Therefore, these findings suggest that potential punishment from others may have been important for indirect reciprocity within a group to be adaptive.

Altruism as a Costly Signal

The reason why altruistic acts can provide indirect benefits to the altruist via an enhanced reputation is due to such acts being costly (Gintis et al. 2001). As a result, these costly acts can signal to others that the actor may be an able coalition partner, potential competitor, or mate. This works on the premise that costly signals of altruism are honest, meaning that they are directly related to the underlying quality of the individual and that they are a handicap (Zahavi 1975). Furthermore, they must also be effectively broadcast to others, beneficial to the receiver and the actor, and a reliable indicator (Eric Alden Smith and Bliege Bird 2000).

An example of how altruism as a costly signal can provide indirect benefits can be seen in the practice of turtle hunting among the Meriam in Australia (Bird et al. 2001). Hunting of turtles is

difficult and risky, so can act as a reliable signal of a hunter's underlying qualities. Therefore when successful, turtle hunters share the catches with all members of their group in large public feasts, instead of keeping it to themselves. This seemingly altruistic act therefore acts as an effective costly signal, as it is a reliable indicator of their ability, a handicap (as the hunter is incurring the cost of giving away their catch), effectively broadcast to other group members and beneficial to the altruist (allows them to display their quality) as well as the receivers (who gain reliable information about the hunter and free turtle meat). As a result, these hunters reap the indirect benefits of increased social recognition and reproductive success (Smith et al. 2003).

Altruism and Mate Choice

Finally, a number of studies have recently explored the possibility that being altruistic provides indirect benefits in mate choice settings. This follows from the view that altruism can be a costly signal, as it can be then used to attract mates by reliably displaying desirable traits to potential mates (as happens with turtle hunters among the Meriam). As a result, it has been shown that individuals will behave altruistically in the presence of potential mates (Bhogal et al. 2016; Farrelly et al. 2007; Iredale et al. 2008; Tognetti et al. 2012, 2016), and also that being altruistic makes individuals more desirable to potential mates (Barclay 2010; Farrelly 2011, 2013, 2016; Moore et al. 2013; Oda et al. 2013; Phillips et al. 2008). Furthermore, there is real world evidence of the indirect benefits in mate choice that being altruistic can bring, as single individuals who are altruistic are more likely to be in a long-term relationship 1 year later than those that are not (Stavrova and Ehlebracht 2015).

Conclusion

As new research into the indirect benefits of altruism built on traditional explanations of how

altruism can be adaptive, we now have a much richer and detailed understanding of all examples of altruistic behaviors and acts that occur in the real world. Although there are different perspectives on how these indirect benefits manifest themselves, what is clear is that the role of enhanced reputation of the altruist is what underlies them. As such, it provides a useful lens through which to view human altruistic acts such as charity, heroism, and generosity amongst others. When understanding that the ultimate explanation for such acts is increased reputation (which in turn can lead to increased survival and/or reproductive success), their origins and motivation become clear. Although this may be a cynical way to view human altruistic acts, it should not ignore the fact that by being "altruistic" is at the heart of our nature as a highly social species.

Definition

Individual differences refer to the many ways in which people differ in terms of traits or characteristics. In the vernacular of behavioral and molecular genetics, individual differences are known as phenotypic variance.

Introduction

The majority of theoretical and empirical literature in evolutionary psychology tends to focus on the numerous ways in which humans are similar. For example, researchers have illuminated how aspects of the human condition such as sexual

attraction, mating strategies, disgust, fear, and even political strategy transcend cultural boundaries. These widespread similarities are a product of our species' shared evolutionary history and so it is somewhat unsurprising, though certainly fascinating, that members of species share so many similar psychological characteristics. Nonetheless, humans across the globe are certainly not identical; indeed, our species is rich in diversity of behavior and psychology. Phenotypic variance (differences in characteristics or traits) is also not surprising as it is a necessary component of evolutionary change. Thus, in order to understand the etiology or underlying causes of human behavior, researchers must recognize both our evolutionary history and the various ways in which individual differences (i.e., phenotypic variance) can affect behavior and psychology. This entry will provide an overview of some of the ways in which researchers in areas such as behavioral and molecular genetics have demonstrated the underlying causes and influential effects of phenotypic differences.

Behavioral Genetics

Behavioral genetics is a scientific field of study that is primarily concerned with understanding the differential influence of genetic and nongenetic factors on phenotypic difference (i.e., individual differences on any observable or measureable trait). In order to determine the estimated genetic and nongenetic influence on phenotypic variance, behavioral geneticists employ a variety of research designs that incorporate at least two genetically related individuals from a given family unit with known genetic relatedness. People in a family unit vary in terms of genetic relatedness based on the amount of genetic material they share. For example, a parent and their biological offspring share 50% of their genetic material, so too do full siblings and dizygotic (fraternal) twins. Monozygotic (identical) twins, however, share 100% of their genetic material. Using information on the degree of genetic relatedness shared between two people from a family unit (e.g., full siblings, dizygotic twins, monozygotic twins) and

information on a phenotype of interest (e.g., height, IQ, aggression) behavioral genetic methodologies can estimate the influence of genetic and nongenetic factors on variance in a phenotype.

Behavioral geneticists interested in examining the causes of phenotypic variance produce estimates of three latent components that represent the sources of genetic and nongenetic factors on variance in the phenotype of interest. The three latent components are *heritability* (symbolized as h^2), the *shared environment* (symbolized as c^2), and the *nonshared environment* (symbolized as e^2). The heritability component represents the estimated amount of variance in a phenotype that is due to additive genetic variance. The shared environmental component refers to the estimated amount of phenotypic variance that is accounted for by experiences and nongenetic factors which are shared between two genetically related individuals and that serve to make them similar to one another on the phenotype of interest. The final component, the nonshared environment, represents an estimate of the amount of phenotypic variance that is accounted for by experiences or nongenetic factors that are unique to two genetically related individuals and that serve to make them less similar (i.e., different) from one another on the examined phenotype. The nonshared environmental component also captures any random sampling or measurement error associated with a study. In total, these components account for all (i.e., 100%) of the variance in a phenotype within the examined sample (Plomin et al. 2013).

Researchers examining the genetic and nongenetic influence on phenotypic variance have applied behavioral genetic methods to a wide variety of phenotypes. Virtually every phenotype that has been subjected to behavioral genetic analysis appears to be influenced by both genetic and nongenetic factors. Importantly, however, these observations have not been derived from a single type of methodology. Indeed, behavioral geneticists rely in a wide variety of methods such the classical twin design, adoption studies, monozygotic twins reared apart studies, and twin-discordant studies. These methods are outlined in brief below.

Classical Twin Design

Known as the workhorse of behavioral genetic methodologies, the classical twin design takes advantage of a natural experiment of nature: twinning. During a standard conception event, one egg is fertilized by one sperm and a single embryo is produced. During twinning, however, the standard conception event is altered. For example, dizygotic (DZ) twins are the result of two separate eggs that are fertilized by two separate sperm. These embryos are no more similar than full siblings are, but they share the same gestational environment at the same time (i.e., during one pregnancy whereas full siblings are the result of different pregnancies). Monozygotic (MZ) twins, however, result when one fertilized egg separates into two embryos. Thus, MZ twins are genetic copies of one another – which is why MZ twins are always the same sex (whereas DZ twins can either be a same- or different-sex pair). The classical twin study is so popular in behavioral genetic research because comparisons between MZ and DZ twins represent an approximation to a controlled experiment in order to estimate the influence of genetic and nongenetic factors on phenotypic variance. However, the manipulation of the genetic relatedness is not completed by an experimenter but by nature.

The underlying logic of the classical twin study is straightforward. Given that twins within a twin set are born at the same time, reared by the same caregivers (typically), attend the same schools, and share many other experiences they are said to share the same developmental environments. Thus, it is assumed that the developmental environments shared between a pair of MZ twins are just as similar as one shared by a pair of DZ twins. Known as the equal environments assumption (EEA), this concept forms a foundation of the classical twin study. While the EEA has been criticized in the past, the empirical *quantitative* literature indicates that it is generally a sound and fair assumption to make (even when violated the estimates of genetic and nongenetic influences are accurate and largely unbiased; see Barnes et al. 2014 and Wright et al. 2015). Given that an equal environment can only result in twins being more similar, any differences

between the sets of MZ and DZ twins must be due to factors that are not shared between the twin sets. Thus, if MZ twins are more phenotypically similar than DZ twins (on the same phenotype), it can be assumed that the increased concordance among the MZ twins is due to the greater similarity in genetic relatedness relative to the DZ twins (MZ twins share 100% of their DNA while DZ twins share 50%). This is the essence of the logic underlying the classical twin study.

Twin studies employ complex quantitative methodologies to compute estimates of genetic and nongenetic influences on phenotypic variance and have refined their methods over the past 30–40 years. Over that time researchers have illustrated that virtually every observable phenotype is impacted by genetic factors. Indeed a recent meta-analysis of 2748 published twin studies covering over 17,000 traits from over 14 million twin pairs indicated that approximately 49% of the variance in all traits was due to genetic factors (Polderman et al. 2015). What this means for the study of individual differences within an evolutionary framework is that any empirical examination needs to be cognizant of the potential influence of genetic factors on phenotypic variance. Note, however, that the classical twin design indicates that not all phenotypic variance is due to genetic factors; nongenetic or environmental factors also clearly play a role in how people differ on a variety of characteristics. This aspect of behavioral genetic methodologies is often glossed over by its critics. While the classical twin design offers a powerful tool in which to elucidate the genetic and nongenetic factors responsible for phenotypic variance, other methods are uniquely suited for examining the influence of nongenetic/environmental factors. The following three subsections outline such methods.

Adoption Studies

Researchers have long recognized the value of adoption studies in determining the influence of genetic and nongenetic factors on individual differences. The rationale of the adoption study method relies on a comparison method. In order to conduct an adoption study, measurements of the phenotype of interest must be available from

the adoptee (child), the adoptive parent(s), and the biological parent(s). If these measures are all available then the researcher can compare the phenotypic similarity between the adoptee and the adoptive and biological parent(s). If the adoptee is more phenotypically similar to the adoptive parent(s) than the biological parent(s) then the researcher can conclude that nongenetic (environmental) factors have more influence than genetic factors. Conversely, if the adoptee is more phenotypically similar to the biological parent(s) than the adoptive parent(s) then the researcher can conclude that genetic factors are more influential than nongenetic factors. The comparison relies on the assumption that the adoptee is not genetically related to the adoptive parent(s) and does not share any substantial environmental factors with the biological parent(s). Sarnoff Mednick and colleagues' (1984) well-known adoption study on criminal convictions provides an illustration of the adoption-based examination of individual differences. Mednick et al. (1984) observed that those adoptees who had *both* a biological parent and an adoptive parent with a criminal record were most likely to also have a criminal conviction. Additionally, the researchers found that adoptees who had a biological risk of crime (i.e., a biological parent with a criminal record) but not an environmental risk (i.e., an adoptive parent with a criminal record) were much more likely to have a criminal conviction than those adoptees with the opposite situation (i.e., an adoptive parent with a criminal record and no biological parent with a criminal record). Given the findings, Mednick et al. (1984) concluded that criminal behavior is influenced more by genetic than nongenetic factors. Nonetheless, the findings also indicate an environmental effect (recall that those adoptees with both an adoptive and biological parent with a criminal record were at the highest risk of having a criminal conviction). Adoption studies are used for numerous other phenotypes and are especially suited to examine the impact of environmental factors on phenotypic variance. However, given that offspring of biological parents only share 50% of their genetic material, there still is the possibility of some unmeasured genetic factors that could

influence the observed associations. The next two subsections deal directly with this issue.

MZ Twins Reared Apart (MZA)

Much like the typical adoption study, MZA research studies rely on a comparison method between the adoptee, biological, and adoptive parents. Additionally, MZA studies allow for comparison between the two monozygotic twins who were adopted apart. Thus, MZA studies allow for multiple ways in which to assess the influence of genetic and nongenetic factors on phenotypic variance. Although multiple comparisons can be made in MZA research, we will focus on the within-twin pair comparisons.

Researchers such as Nancy Segal (e.g., Segal 2000) have used the MZA method to illustrate the often uncanny similarities between genetically identical people who were raised in different environmental conditions. Working with other researchers at the University of Minnesota, Segal employed data from the Minnesota Study of Identical Twins Reared Apart. Given the rarity of adopted apart MZ twins the pool of respondents available to the researchers was relatively small. Nonetheless, the study obtained exceptionally in-depth information on over 100 pairs of MZ twins who were adopted apart. For virtually every phenotype examined by the researchers it was observed that the MZ twins resembled each other more than they resembled their adoptive parents. Furthermore, in what is truly an incredible finding, the MZA twins were observed to be *as similar* on a variety of phenotypes as MZ twins who were reared together. Thus, the effect of being raised apart for MZA twins was minimal in terms of phenotypic variance. The MZA method is an exceptionally strong method for illustrating the effect of genetic factors on individual differences but it is not the only way in which MZ twins have helped inform behavioral genetic research. Indeed, MZ twins have been vital to illustrating what *nongenetic* factors have an influence on phenotypic outcomes beyond the influence of genetic factors. The next subsection describes the MZ twin discordance method and how it is used to isolate nongenetic (environmental) effects on individual differences.

MZ Twin Discordance Methods

Although behavioral genetic research is often perceived as seeking to only identify genetic influences on phenotypic variance, the methods used in behavioral genetic studies are perfectly suited to assess nongenetic (environmental) influences as well. Indeed, given that virtually all phenotypes are influenced by genetic factors those methods which do not account for the influence of genetics are likely confounded (i.e., they are unable to rule out the possibility that genetic factors are influencing the outcome). Thus, methods which examine the influence of environmental factors that are also genetically sensitive are ideal for isolating nongenetic effects. Perhaps the most powerful method for doing so is the MZ twin discordance method.

Recall that MZ twins share 100% of their DNA. Additionally, by definition MZ twins also share 100% of their shared environment. Thus, the only way in which MZ twins will exhibit phenotypic variance will be due to unique, nongenetic factors. These factors are referred to as nonshared environmental factors. Such influences can be isolated using the MZ twin discordance method. The process is relatively simple: a researcher creates difference scores of a particular phenotypic measure by subtracting one MZ twin's score from their co-twin's score on the same measure. This process is done for all variables of interest. The difference score is a measure of the nonshared environmental component of the variable of interest since it measures the *discordance* within the MZ twin pair. Using quantitative methods, a researcher can then examine the associations between multiple difference scores to assess whether a particular component of the nonshared environment is influential in terms of why MZ twins differ on an outcome measure of interest. Doing so controls for the effects of shared genetic and shared nongenetic factors on the phenotype and isolates a particular environmental effect. Thus, the MZ twin discordance method is a powerful and robust method to identify *environmental* influences on individual differences. To illustrate, Nedelec and colleagues (2016) employed the MZ twin discordance method to examine the effect of a variety of criminologically relevant

environmental variables on long term antisocial behavior and substance use. The researchers observed that most of the associations were not statistically significant (indicating that long term antisocial behavior and substance use are primarily the result of genetic factors, or unobserved nonshared environmental factors). However, they did note that twins who had more exposure to delinquent peers relative to their co-twins engaged in higher rates of antisocial behavior and substance use as adolescents than their co-twins. The effect, however, did not persist into adulthood. Nonetheless, this genetically sensitive method provided strong support for an environmentally based theory of adolescent delinquent behavior. These types of studies once again highlight the need to account for genetic influence when examining individual differences on phenotypes of interest to social scientists, including evolutionary psychologists.

As a further example, life history theory (LH) indicates that organisms take key clues from their environmental conditions to guide the allocation of resources to development, mating strategies, and reproduction. Numerous evolutionary psychologists have applied this established mid-level evolutionary theory to human behaviors. Researchers have illustrated, for example, that environments which are highly unstable tend to engender an earlier timing of puberty, earlier timing of first sexual behaviors, and earlier timing of first pregnancy. However, all of these phenotypic outcomes have been shown to be partially heritable. Thus, the potential for genetic confounding is a valid concern. Incorporating a genetically sensitive design, such as the MZ discordance design, could yield results that are not potentially confounded by unmeasured genetic factors.

While behavioral genetics methods are extremely valuable in illustrating the influence of environmental and genetic factors on phenotypic variance, they do not indicate which particular genes are responsible for the variance. The next section describes processes of examining individual differences which focus on identifying specific genes and/or clusters of genes that can affect phenotypic variance.

Molecular Genetics

The identification of genetic influence on phenotypic variance outlined above results in understanding the overall or additive effect of genetic factors. In order to identify specific aspects of that overall influence, molecular genetic methodologies are employed. In general, molecular genetic research on phenotypic variance is focused on three general methods: candidate gene studies, gene-by-environment interactions, and gene-environment correlations. Each of these methods is briefly described below.

Genome-Wide Association Studies (GWAS)

As noted above, behavioral genetic studies have convincingly illustrated the influence of additive genetic effects on phenotypic variance across almost all aspects of the human condition. However, in order to identify which specific genetic material is affecting the observed variance molecular researchers seek out specific genes using candidate gene methodologies. Thanks to the incredible technical advances in researchers' ability to scan a large sample of genetic material provided by research participants, these studies are able to correlate any observed difference in specific genes with reported or observed differences in phenotypic outcomes. Often referred to as genome-wide scan or GWAS, the method relies on genetic differences at certain places in the human genome. For example, genes can vary in a number of ways but one way that is convenient for research is called a single-nucleotide polymorphism. Briefly, genes are comprised of four different bases or nucleotides (A, C, G, and T) that make up the genetic alphabet. At various segments along strands of DNA, contiguous base pairs work together to code for a particular function. These contiguous base pairs are called genes. Most people's genes are identical across 99% of the genome. The reason for such similarity is because humans are from the same species. The remaining 1%, however, can lead to some drastic differences in personality, behaviors, health outcomes, and a number of other factors. Polymorphic genes – those which have two or more versions in the population – can lead to such

phenotypic variance. One way genetic variance can arise is via single nucleotide polymorphisms (SNPs), which are genes that vary in the population due to one base pair (single nucleotide) differing across individuals. While most SNPs (pronounced “snips”) have little to no effect, some have been identified as affecting a variety of outcomes related to neuronal functioning, personality, and behaviors. Studies which employ GWAS methodologies scan the genomes of participants to identify SNPs and any association with a variety of outcomes. GWAS and similar techniques (e.g., genome-wide complex trait analyses or GCTA) have been applied to outcomes ranging from psychiatric disorders to overall health to impulse control and intelligence (Barnes et al. 2014). One caveat that is often brought to bear in candidate gene studies is that the overall influence of a SNP is often minimal. This is not a surprise given that behavioral and psychological outcomes are so complex. However, individual differences in these outcomes would not occur if not for the genetic variance seen in GWAS analyses (i.e., while the effect is minimal with one SNP, the effect would be null if not for the difference between SNPs; see Dawkins 2006).

Gene by Environment (GxE)

While candidate gene studies provide valuable information regarding the underlying specific genetic material influencing individual differences, it is always key to remember that genes also interact with environmental factors to produce phenotypic variance. Thus, molecular geneticists also examine how specific polymorphisms affect phenotypic outcomes when paired with particular environmental conditions. As with any analysis of interactive effects, GxE research has indicated that certain genetic influences are enhanced or dampened when paired with certain environments (and vice versa). An informative way to conceptualize this dynamic is to think of two circles which represent the risk associated with a particular outcome. One circle represents the genetic risk (e.g., a candidate gene) and the other circle represents an environmental risk (e.g., abusive home environment). While on their own each aspect increases the likelihood of some

outcome, but the risk (or probability) of the outcome is greatest where the two circles overlap (i.e., like a Venn diagram). Perhaps the most well-known example of GxE research that illustrates this point was conducted by Caspi, Moffitt, and colleagues in 2002. The researchers were interested in assessing the independent and interactive effects of the MAOA genotype and an abusive rearing environment on antisocial behaviors. Caspi et al. (2002) observed that the effect of the risk allele for MAOA (a version of the gene that had been independently associated with antisocial outcomes in prior research) had a greater effect on the likelihood of antisocial behavior when those who possessed it were also raised in an abusive family. Importantly, the effect of these two factors on their own was minimal compared to the interactive effect. Other researchers studying a wide variety of phenotypic outcomes have illustrated similar GxE effects.

Gene-Environment Correlation (rGE)

While GxE research can illustrate the manner in which genetic and environmental factors combine to influence phenotypic variance, gene-environment (rGE) research highlights how genetic factors can lead to variance in exposure to different environments (Beaver 2009). In other words, this type of research illustrates that genetic variance can lead to phenotypic differences in individuals but can also affect environmental variance as well. Thus, in rGE research environmental factors are considered the outcomes (in the same manner as phenotypes in behavioral genetic and other molecular genetic research). In order to better understand this counter-intuitive claim, the three varieties of rGEs are discussed below.

Passive rGE

The passive rGE typology illustrates that children receive both genetic and environmental influences from their parents (provided they are raised by their biological parent or parents). As a result of the two influences emanating from the same source (i.e., parents), they are bound to be correlated. Consequently, the environment in which a child is raised is an expression of the genetic propensities that they share with their biological

parents. A common example is the observed association between the number of books in a household and a child's eventual cognitive abilities. Social scientists have long observed such an association and have assumed that if one has more books in their house, one will help increase the cognitive capabilities of one's child. However, given that a child shares 50% of their genetic material with each of their parents, they will also share the propensities towards activities that the parents also enjoy (e.g., reading). Additionally, behavioral genetic research has illustrated that cognitive ability is highly heritable. Thus, the books may not be the sole cause of the observed variance in cognitive ability but rather is a manifestation of genetically influenced propensities (i.e., people who have higher cognitive ability tend to read more and have more books in their home; they also tend to have children who also possess strong cognitive abilities). Consequently, passive rGE research illuminates how a developmental environment can be correlated with, but not necessarily cause, phenotypic variance in children.

Active rGE

Active rGE refers to the nonrandom selection into various environmental conditions and situations (e.g., employment type, hobbies, peer groups) that are driven in part by genetic propensities that are best expressed within the selected environment (Plomin et al. 2013). In other words, people often self-select into environmental conditions that suit their personalities and other genetically influenced propensities (and actively select away from environments that do not suit those propensities). This process is often referred to as *niche-picking* and research has illustrated that it occurs partially due to genetic factors (i.e., the niche to which one selects is associated with a nonzero heritability value). Finally, behavioral and molecular genetic researchers have also shown that as people age and gain increased degrees of independence the active rGEs become much more salient. Thus, while it may at times appear that environmental conditions lead to individual differences it is, according to active rGE research, in fact the opposite: variance in environmental conditions for many individuals is due in part to variance in genetic factors.

Evocative rGE

Psychology has long illustrated that different people elicit or evoke different reactions from others. Variance in factors such as personality, physical attractiveness, and sense of humor (among other traits) across individuals leads to differential social interactions with others. Stated differently, genetic differences generate phenotypic variance which in turn elicits differential reactions from one's environment. As a result, there is a statistical association between an individual's genotype and their environment. Additionally, researchers have shown that this evocative process exhibits a nonzero heritability value. Along with passive and active rGEs, evocative rGEs illustrate the need to recognize the ever-present influence of genetic and nongenetic factors when examining phenotypic variance, including in the context of evolutionary processes.

Conclusion

While evolutionary psychology is often focused on how humans are similar across time and cultures, it is still important to recognize the manifest ways in which individual differences arise and can influence behavior and personality. Indeed, without variance in terms of genetic differences, the processes of natural and sexual selection are unable to function. Thus, as a discipline evolutionary psychology has worked to incorporate a greater increase of the research and methodologies of behavioral and molecular genetics. Scholars such as David Buss (2009) and Penke (2009) have described the various ways in which evolutionary psychology can integrate examinations of individual differences and how such examinations can be employed to test, as well as refine, theories derived from an evolutionary paradigm (e.g., life-history theory, frequency-dependent selection, mutation load, among others). For example, Buss (2009) argues that individual differences in personality should be viewed as strategic differences that individuals can employ when provided with a variety of environmental challenges that are relevant to survival and reproduction. Additionally, both

Buss (2009) and Penke (2009) indicate that the theoretical scaffold of evolutionary psychology can be employed to provide ultimate explanations for the observed individual differences highlighted in the fields of behavioral and molecular genetics. The summary provided in this chapter further illustrated the variety of ways such integration can enhance our understanding of why humans behave and think the way that they do. Additionally, it can help highlight the reasons why people differ in a multitude of ways associated with psychology's primary foci.

Individual Variations in Attachment

Tommie Forslund¹ and Pehr Granqvist²

¹Uppsala University, Uppsala, Sweden

²Stockholm University, Stockholm, Sweden

Definition

Individual variations in attachment denote interindividual variations in the organization or quality of attachment behavior in relation to the attachment figure, particularly observable when the attachment system is activated following external or internal cues of threat. Individual variations in attachment are typically described using two dimensions (secure/insecure, organized/disorganized) subsuming four distinct categories (secure, insecure-avoidant, insecure-ambivalent/insecure-resistant, and insecure-disorganized/disoriented). Profound difficulties in forming attachments to others (i.e., reactive attachment disorder [RAD]) are typically reserved for children who have not had any consistently available caregiver (e.g., children growing up in some institutions). Variations in attachment quality are

reliably predicted by the caregiver's pattern of responding to the child's signals (e.g., sensitivity), with characteristic forms of caregiving believed to be internalized as the child's internal working models (IWMs, cognitive-affective representations) of self and others, particularly as regards the attachment figure's availability for protection and support (Bowlby 1973).

Introduction

Attachment theory involves postulates about species-normative development as well as development of individual variations. John Bowlby, the founder of attachment theory (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)), contested the theories of attachment available at the time (see ► [“Psychodynamic Foundations”](#)). Seeking an alternative explanation, he came to devote a great deal of effort into formulating the core tenets of attachment theory and its normative aspects, drawing from ethology, cybernetics, and cognitive psychology (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). These aspects include his conceptualization of the attachment system as a behavioral control system with a function of maintaining proximity to caregivers, retained through natural selection as it served an adaptive function of increasing chances of survival against predators and other natural dangers (see ► [“Infant Survival”](#)).

Bowlby was also convinced that there are interindividual variations in attachment quality, depending on how available the caregivers have been and how effectively they have responded to the child's signals (i.e., their sensitivity). Bowlby had, for example, found in his own work that lengthy separations caused frustration in children which seemed to follow a sequence of phases in the form of protest, despair, and (if not terminated) detachment (Bowlby 1982; Robertson and Bowlby 1952). Indeed, infants and young children were often showing signs of “insecurity” in relation to the caregiver following long separations, for example, in the form of initial avoidance and unresponsiveness upon reunion with the caregiver. That Bowlby argued for individual

variations in attachment is also clear from his emphasis on the importance of the quality of children's attachment to their caregiver(s) for the development of the self and social development. Bowlby had, for example, found in his own research that delinquent and aggressive children had experienced markedly more frequent early separations from their caregivers than other children (Bowlby 1944).

However, in comparison to Bowlby's careful efforts in precisely delineating the core tenets of the attachment system and the normative aspects of attachment, he did not get around to "systematizing" individual differences in attachment. This was partly due to lack of an empirical method for systematically examining variations in attachment. In his groundbreaking research into attachment, Bowlby therefore focused on the basic need for a continuously available caregiver for the development and maintenance of attachment bonds and the untoward effects of serious separations from or loss of caregivers, which were readily observable during the postwar era. Indeed, in delineating the problems yet to be solved regarding patterns of attachment (e.g., individual variations), Bowlby asked: "...in terms of what dimensions are variations best described. . . what antecedent conditions influence the development of each variety of pattern. . . how is each pattern related to subsequent personality development and health" (Bowlby 1982, 1997, p. 331). Attachment theory therefore owes much to Bowlby's close collaborator Mary Ainsworth and her colleagues and students, most notably Mary Main, for the systematic mapping of individual variations in attachment security and organization. Individual variations in attachment, as initially described by Bowlby and subsequently furthered by the research that followed, are elaborated below.

Bowlby's Notion: Variations in Internal Working Models of Self and Others

As outlined by Bowlby (1982), children come into the world endowed with attachment behaviors and prepared to form attachments, doing so to caregivers who are sufficiently available and

responding to their signals, particularly during stress when the attachment system is activated (see ► ["Offspring-Parent Attachment"](#)). Bowlby and Ainsworth both argued that "strength" of attachment is a misleading term. Children are either attached to their caregivers or not; what varies is the quality or organization (see below) of children's attachments to their caregivers. Rather than systematizing individual differences in attachment, Bowlby focused his theoretical efforts on how variations in attachment-related experiences with caregivers become manifested, eventually leading to observable differences in children's overt attachment behavior.

Drawing from cognitive theory (Craig 1943; Young 1964), Bowlby (1973) argued that individual variations in attachment-related experiences are manifested in cognitive-affective representations of self and others, which he termed internal working models (IWMs, see Bretherton and Munholland 2008). The IWMs are thought to include expectations of others' behaviors in relation to the self and the availability of others (particularly in attachment-related situations), as well as expectations on the self and its effectiveness in affecting the environment (i.e., others, most notably the caregivers). Bowlby argued that IWMs of self and others are complementary as the child gets to know itself as a person through how she/he is responded to by the caregiver (e.g., in line with psychodynamic object relations theories (see ► ["Psychodynamic Foundations"](#)). For example, a child that is responded to sensitively and lovingly by the caregiver is thought to construct both a model of others as loving and available in times of distress and a complementary model of the self as lovable and effective in getting what she/he needs from others.

Drawing from information processing and memory theories, Bowlby also argued that experiences of insensitive caregiving lead to the creation of incoherent (or multiple) IWMs, whereby the later emerging explicit layer of the IWMs differs from the implicit layer (Bowlby 1973). In line with Freud's ideas and those of psychoanalysis, but reformulated in modern information processing and memory function terms, he also argued that experiences of insensitive caregiving

and creation of incoherent IWMs necessitate the use of psychological defenses, such as defensive exclusion, to protect the individual against anxiety and associated dysfunctional behaviors (see ► “Psychodynamic Foundations”).

Importantly, Bowlby stressed that once IWMs are formed, they will come to guide children’s attention, behavior, and displays of emotion in future attachment-related situations with the caregiver (and others), as well as how children perceive various situations. Children who have become attached are therefore, for better and worse, thought to become active cocreators of the experiences they subsequently receive. That is, children will tend to act in ways that confirm their IWMs, which contributes to making them stable and partly resistant to change. Indeed, Bowlby noted that the high synchrony typically observed between attached children and their caregivers should be seen as a result of both the caregiver and the child adapting to one another. Drawing from Piaget (1955), Bowlby also argued that we tend to make small corrections to our models, which also contributes to make them stable since information is assimilated into the current models. However, given sufficiently strong new input, substantial change will occur through accommodation. Thus, the attachment system is seen as an open system, and the quality of attachment is therefore not set in stone (see Hoffman et al. 2006, for an attachment-based intervention).

Systematic Mapping of Individual Differences: Variations in the Organization or Quality of Attachment Behavior

Single Behaviors as an Insufficient Index of Attachment Quality

Bowlby argued that displays of attachment behaviors depend on multiple conditions, and he therefore outlined that observations of the quality of children’s attachment to their caregivers must (as a minimum) include “mother’s whereabouts and movements, presence or absence of other persons, the state of the non-human environment, and the state of the child” (Bowlby 1982, 1997,

p. 335). Accordingly, research has found that no single behavior is enough as an index of attachment quality (Ainsworth et al. 1978; Bowlby 1982). Two explanations for this are that the attachment system is activated by external and internal cues of threat and that it develops into a complex goal-oriented system that can flexibly make use of various behaviors (see “Evolutionary Foundations to the Attachment System and Its Functions”). First, as outlined by Bowlby, children’s “set goal” regarding the degree of proximity they desire to their caregivers varies momentarily depending on both external cues (e.g., strange or familiar environment, presence of strangers or not) and internal cues (e.g., child healthy or sick). Second, due to the complex goal-corrected nature of the attachment system, a child may also use signaling behavior in one situation, such as crying or smiling/vocalizing, and active locomotor behavior such as following the caregiver in another. Children moreover show interindividual differences in their tendencies toward various reactions, partly due to their biological characteristics (e.g., temperament; Vaughn et al. 2008). Using one single behavior to capture such a complex phenomenon as attachment quality, and trying to examine attachment in terms of “strength,” is therefore insufficient, indeed misleading. The insufficiency of any single behavior as an index of the quality of attachment is perhaps best exemplified with displays of aversive signaling behavior (e.g., crying) upon (short) separations from the caregiver, which is often mistakenly taken as an indication that children are securely attached (and conversely, that lack thereof is a sign of insecurity). However, not all secure children cry and protest separations, and some insecure children also display such aversive signaling behavior (e.g., Ainsworth et al. 1978).

Organization of Attachment Behaviors as an Index of Attachment Quality: Children’s Ability to Use the Caregiver as a Secure Base and a Safe Haven

One of the great accomplishments of Ainsworth (Ainsworth et al. 1978) was how she nonetheless

managed to devise a way to systematically examine the quality of children's attachment to their caregivers. She did so by taking into account Bowlby's ideas about the interaction between the attachment system and other behavioral systems, most notably the exploratory system (see ► [“Offspring–Parent Attachment”](#)), and his ideas about the complex goal-corrected functioning of the attachment system.

First, Bowlby argued that the attachment system interacts with an exploratory system and that the two systems are mutually inhibiting. That is, children are seen as having an innate desire to explore the environment (which facilitates learning) so that when there are no cues of threat, and the activation of the attachment system is low, children can explore the environment freely. However, upon signs of danger, the exploratory system becomes inhibited and the attachment system activated, typically making children retreat to their caregiver for protection and comfort. Importantly, Bowlby argued that secure attachment facilitates exploration. Children who feel that their caregiver is available for protection if danger should arise (“felt security”) can devote less energy (or epistemic space) into monitoring their caregivers and potential dangers and instead focus their energy on exploration (see ► [“Effects of Attachment Quality and Organization,”](#) for a discussion of how attachment may affect subsequent development through effects on the exploratory system). An important part in Ainsworth solving the puzzle was therefore that she managed to devise a method for examining the balance that (some) children manage to strike between attachment behaviors and exploratory behaviors.

Second, and referencing Bowlby's postulate that the attachment system becomes goal-corrected and can use various behaviors to reach its set goal, she devised a procedure that captures how children “organize” their behavior in relation to the caregiver, rather than focusing on any single behavior. Variations in attachment are thus not seen in any specific behavior, but in the pattern or “organization” of behavior in relation to the caregiver (Sroufe and Waters 1977; see below for specific “patterns of organization”). Ainsworth described the functions that caregivers need to fill

for children to be securely attached, simultaneously delineating what is meant by a “secure organization of attachment behaviors,” using two related terms. First, the caregiver must be a “secure base” for children, a reference point from which they can explore the environment freely. That is, caregivers must convey to the child that the environment is safe and that the caregiver is monitoring the child's whereabouts should danger arise. Moreover, the caregiver must also function as a “safe haven” to which the child can retreat upon signals of threat, being warm and accepting of the child's bids for proximity, cooperating with the child, and responding sensitively to the child's signals. When caregivers fulfill these functions, their children are seen to display a balanced and flexible (e.g., “secure”) organization of behavior, exploring the environment when there are no signs of danger and retreating to the caregiver for comfort when distressed. Wanting to show his appreciation of Ainsworth's contributions to attachment theory, Bowlby named his final book “a secure base” after her concept (Bowlby 1988).

The Development of the Strange Situation Procedure and Measurement of Children's Organization of Attachment Behavior

Using Bowlby's ethological approach, Ainsworth initially conducted extensive naturalistic observations in Uganda of children and their caregivers during the children's first years of life. She observed that children tended to show three distinct patterns in their organization of attachment behaviors in relation to their caregivers, patterns which tended to be associated with the caregiver's sensitivity in responding to the children's signals.

However, when Ainsworth sought to replicate and expand on her findings in American children, she ran into a notable problem. Whereas her mere presence as a white woman in Uganda (a strange and potentially threatening stimulus) had activated the attachment systems of the Ugandan children, making it possible for her to observe variations in the organization of attachment

behaviors, this was not the case in American children. She therefore came to devise the semi-structured laboratory observation called “the strange situation procedure” (SSP), which is still to date widely used for examining variations in attachment security and organization in infants (aged 12–18 months).

The SSP was specifically designed to enable observation of how children organize their attachment behavior in relation to the caregiver by using well-known triggers of the attachment system such as an unfamiliar environment, the presence of a stranger, and two (short) separations from the caregiver. The child (in the caregiver’s presence) is first given some time to explore the room and its play materials after which stress is gradually induced by a stranger entering the room, the stranger trying to interact with the child, the caregiver shortly leaving the room (leaving the child with the stranger), and (after a short reunion) the caregiver leaving the child alone in the room for a short time (before a second reunion). Importantly, the SSP is meant to be mildly to moderately (not very) stressful. The goal is to create a situation that is just enough stressful to activate the child’s attachment system so that variations in the organization (or lack thereof) of behavior can be observed. Indeed, research has shown that too much stress, such as from letting separations go on too long despite marked distress, may make the behavioral organization of otherwise organized children break down (Granqvist et al. 2016).

The SSP was moreover designed to activate the exploratory system. The physical environment of the SSP is not meant to be threatening. On the contrary, it is designed to be welcoming and interesting and is usually filled with age-appropriate toys to trigger children’s desire to explore. In other words, by triggering both the exploratory system and the attachment system, the SSP enables examination of whether children can use the caregiver as a secure base from which to explore and as a safe haven to return to for comfort when distressed. Importantly, by triggering both systems, children’s ability to strike a flexible balance between the two can be observed.

Ainsworth and her colleagues conducted a groundbreaking study of more than 100 children

and their caregivers, wherein 26 dyads were followed particularly intensively using over 70 h of home observations to examine caregiver sensitivity. When the children were 12 months, they were subsequently seen along with their caregiver in the SSP. Using four different behavioral scales (i.e., proximity-seeking, contact-maintaining, avoidance, and resistance) and focusing on variations in children’s organization of behavior, three distinct patterns emerged. Although behavior throughout the observation was important, behavior in relation to the caregiver in the two reunion episodes was particularly informative. Notably, Ainsworth et al. (1978) found a very strong correlation between the caregiver’s sensitivity in relation to their children’s signals during the first year and the children’s attachment security.

Organized Patterns of Attachment: Secure, Insecure-Avoidant, and Insecure-Resistant/Insecure-Ambivalent Attachment

Secure Attachment

Children classified as secure are characterized by a flexible balance between attachment behavior and exploratory behavior in the SSP. They typically use the caregiver as a secure base during the initial pre-separation episodes, playing elaborately with the toys and sharing their experiences with their caregiver. Secure children vary in their reactions upon the entry of the stranger, but most eventually accept interacting with the stranger. Secure children again show varying reactions during the two separation episodes, with some children displaying aversive signaling behavior (e.g., crying, searching), whereas other children are content exploring (see “[Secure Attachment](#)” for a fuller description).

Secure children who have become distressed by the separation use the caregiver as a safe haven in the reunion episodes. That is, they approach the caregiver and/or signal that they want proximity and comfort (proximity-seeking behavior), and they are effective in maintaining the contact for as long as they need in order for the attachment system to become inactive, for example, clinging

on attempted release (contact-maintaining behavior). Thus, they are eventually soothed and can go back to exploring the play material. Secure children who have not become distressed during separation tend to greet the caregiver happily and to try to involve the caregiver in their play. Importantly, this description of variations in “specific” behaviors shown by secure children underscores the need to examine the organization or patterning of behavior and not focus solely on any individual behavior.

Ainsworth and colleagues found that secure children tend to have caregivers who, during the home observations, were sensitive, perceiving the children’s signals and responding to them timely and appropriately. They both acted as a secure base, supporting children’s exploration, and as a safe haven, effectively comforting the children when distressed. Meta-analytical research has indicated that about two thirds of children tend to be securely attached in normative samples, with lower rates in children from high-risk groups (van IJzendoorn and Sagi 1999). Secure attachment is associated with positive development, such as high social competence and low levels of behavior problems (see ► [“Effects of Attachment Quality and Organization”](#)).

Insecure-Avoidant Attachment

Avoidant children show another distinct pattern in the SSP, which is seen as organized but less optimal than the secure pattern. First, avoidant children’s play often lacks the complexity shown by secure children, being stereotypic and shallow, and they share their experiences with the caregiver less often than secure children do. Thus, avoidant children’s ability to use the caregiver as a secure base seems to be impaired. Avoidant children, who typically do not protest during the separations, are particularly characterized by their behaviors in the reunion episodes, whence they often avert their gaze, turn and move away, or actively ignore the caregiver for an extended time (e.g., avoidant behaviors). Thus, their level of proximity-seeking and contact-maintaining behavior is often conspicuously low, and they do not show the same striking specificity of preference for the caregiver. The avoidant pattern is

often referred to as a “minimizing strategy,” denoting these children’s limited display of attachment behaviors and affect in relation to the caregivers (Cassidy 1994). (See ► [“Organized-Insecure Attachment”](#) for a fuller description.)

Importantly, avoidant attachment cannot be explained by stable dispositions such as temperament (Vaughn et al. 2008). Ainsworth and her colleagues, and the research that subsequently followed (Isabella and Belsky 1991), have shown that avoidant children tend to have caregivers who are less sensitive than caregivers of secure children. Specifically, caregivers of avoidant children have been found to more often “reject” their children’s bids for proximity and comfort (Ainsworth et al. 1978). Meta-analytical research has found that about 15–20% of children in normative samples tend to be avoidant (van IJzendoorn and Sagi 1999). Avoidant attachment is a risk factor for suboptimal development, for example, in the form of behavior problems (see ► [“Effects of Attachment Quality and Organization”](#)).

Insecure-Ambivalent/Insecure-Resistant Attachment

Ambivalent (or resistant) children show another distinct pattern of organization in the SSP. They often have difficulties with exploration, and it is not uncommon for them to show negative affect and distress even before the stranger enters the room, demanding attention by and proximity to the caregiver. They often retreat to the caregiver when the stranger enters and show limited acceptance of interaction with the stranger. Thus, their ability to use the caregiver as a secure base is impaired. (See ► [“Organized-Insecure Attachment”](#) for fuller description.”)

The ambivalent children typically show intense negative affect during the separations and often show moderate to high levels of proximity-seeking and contact-maintaining behaviors in the reunion episodes. Their behavior is, however, particularly characterized by an inability to be soothed by the caregiver’s overtures in the reunions, in combination with angry behaviors such as arching the back when in close contact with the caregiver and/or batting or throwing

away toys (resistant behaviors). Thus, the caregiver is insufficient as a safe haven. Ambivalent/resistant attachment has been described as a “maximizing” strategy, denoting these children’s heightened activation of the attachment system and high frequency of attachment behavior (Cassidy 1994).

Ambivalent/resistant children tend to have inconsistently sensitive caregivers, sometimes responding sensitively and sometimes not (Ainsworth et al. 1978; Cassidy and Berlin 1994). Meta-analytical findings have indicated that about 5–10% of children in normative samples are ambivalently attached (van IJzendoorn and Sagi 1999). As for avoidant children, this pattern is also associated with suboptimal development in the form of behavior problems and lower social competence (see ► “Effects of Attachment Quality and Organization”).

Insecure-Disorganized/Insecure-Disoriented Attachment

A minority of children were found impossible to classify using Ainsworth’s coding scheme to the SSP (Main and Solomon 1990). For example, some children behaved as an avoidant child in one reunion, but as an ambivalent child in the other one, or showed avoidant and ambivalent behaviors simultaneously. Some children also showed inexplicable, bizarre, or fearful behaviors in the presence of the caregiver, such as falling prone on the floor or freezing/stilling or covering the face with the hand or approaching the stranger upon seeing the caregiver in the reunion episodes (see ► “Disorganized Attachment and Reactive Attachment Disorder” for a fuller description).

Mary Main, a student of Ainsworth, discovered that the children showing these behaviors had one thing in common: an inability to maintain an organized strategy of behavior in relation to their caregiver (hence the label “disorganized”). Thus, whereas the avoidant and ambivalent patterns are also insecure, disorganized attachment differs from these patterns in the form of a breakdown in behavioral and attentional strategies (Hesse and Main 2000). Accordingly, disorganized attachment is seen as even less optimal than the organized-insecure patterns.

Mary Main, together with her close collaborator Erik Hesse, has theorized that an important antecedent to disorganized attachment is fear in relation to the caregiver and that disorganized attachment may follow from frightening/frightened behaviors on behalf of the caregiver (Hesse and Main 2000). Upon activation of the attachment system, disorganized children are thought to become stuck in an unsolvable approach/avoidance conflict of being both motivated to approach their caregiver for support and simultaneously being alarmed by the caregiver and motivated to avoid the caregiver. This unsolvable conflict is thought to lead to the breakdown in behavior shown by disorganized children. Importantly, and to avoid common misconceptions, disorganized children are attached to their caregivers. Being attached, and thereby motivated to approach the caregiver upon activation of the attachment system, is a prerequisite for disorganized attachment.

Research has shown that disorganized attachment is common in abused and maltreated children, supporting Main and Hesse’s theoretical proposal of fear as key in disorganization (Cyr et al. 2010). However, research has also shown that 15% of children in normative samples tend to be classified as disorganized (van IJzendoorn and Sagi 1999). Importantly, not all children assigned a disorganized classification have been maltreated, which is another common misconception. For example, research has also shown that unresolved traumatic experiences in the caregivers can lead to momentary frightening/frightened parenting behaviors in the absence of maltreatment, such as becoming dissociative and unable to contact and thus leaving the child psychologically alone, or being momentarily frightened by the child. Such frightening/frightened behaviors have in turn been shown to predict disorganized attachment (Schuengel et al. 1999).

It cannot be stressed enough that one cannot infer a characteristically disorganized attachment system merely from observing disorganized behaviors. Research has, for example, also found that temporary over-stress and neurological vulnerability, such as having early difficulties regulating attention and emotion at birth, are risk factors for disorganized behaviors (Granqvist

et al. 2016; Padron et al. 2014). There is also an association between high levels of ADHD symptoms and disorganized behaviors (Forslund et al. 2016), and pharmacological treatment of ADHD has been found to lead to large reductions in disorganized behaviors (Storebø et al. 2014). Thus, neurological problems may result in children behaving in disorganized ways without these behaviors necessarily being the result of a certain relational history with caregivers.

Disorganized attachment is the category of attachment that shows the strongest association with concurrent and later problems, particularly with externalizing problems such as aggression and symptoms of oppositional defiant disorder (see ► [“Effects of Attachment Quality and Organization”](#)).

Following the addition of the disorganized category, variations in attachment may be conceptualized using two dimensions: secure vs. insecure (avoidant, ambivalent, disorganized) and organized (secure, avoidant, ambivalent) vs. disorganized. Children classified as disorganized are typically given (if possible) a best-fitting secondary classification using Ainsworth’s original coding scheme. That is, if the child had been able to maintain an organized strategy, which one would that have been?

Reactive Attachment Disorder

A (small) minority of children do not show clear signs of attachment behaviors in relation to their caregiver and can therefore not be captured with the main dimensions of attachment quality and organization (Dozier and Rutter 2008). One cluster of children shows a marked unresponsiveness to the caregiver in the SSP, neither initiating interactions with the caregiver nor responding to the caregiver’s bids for interaction and/or bids to comfort the child. Another cluster of children fails to check back with the caregiver in the unfamiliar setting of the SSP and exhibits a lack of age typical social reticence by showing a willingness to go off with and approaching the stranger. These patterns are considered two subtypes of reactive attachment disorder (RAD): an emotionally withdrawn/inhibited type and an indiscriminately social/disinhibited type, respectively (Zeanah

et al. 2011) (see ► [“Disorganized Attachment and Reactive Attachment Disorder”](#) for a fuller description).

RAD is mainly found in children who have experienced severe social deprivation, being rare to nonexistent in low-risk samples but among the most common problem found in children who have experienced institutionalization (Zeanah et al. 2011). RAD is therefore thought to stem from a lack of a consistently available caregiver to direct attachment behaviors toward, with a severe lack of species-typical experience compromising the development of the attachment system. Attachment disorders often remit when caregiving conditions improve, such as following adoption, attesting to the resilience of the attachment system, but attachment disorders can persevere long after adoption, possibly indicating that the attachment system may have a sensitive period for typical development to occur (Dozier and Rutter 2008).

Conclusion

Bowlby argued that children, depending on the caregiver’s sensitivity, develop interindividual variations in attachment quality that are manifested in cognitive-affective representations of self and others. Subsequent research, most notably by Mary Ainsworth and Mary Main, has supported Bowlby’s claims and furthered them by systematizing individual differences in attachment. Specifically, Ainsworth discovered three organized patterns of attachment that vary in quality (e.g., secure, insecure-avoidant, insecure-ambivalent/insecure-resistant) and Main a group of children that fail to maintain an organized strategy, the “disorganized-disoriented” category. A final group of children, who have not had any consistently available caregiver, develop attachment disorders, as captured in reactive attachment disorder.

Synonyms

Aggression; Dominance; Formidability; Power

Definition

In humans, individuals that impose costs are those who signal both an ability and a willingness to inflict harm upon others.

Introduction

Traits that successfully signal an ability and willingness to impose costs comprise a dominance profile. Attaining social rank through dominance is reliant on an individual’s propensity to induce fear of psychological, material, and physical costs that the individual may impose upon their conspecifics (Buss and Duntley 2006; Chance 1967). Dominance has a deep phylogenetic legacy and likely persisted due to the prevalence of intergroup conflict throughout human prehistory that created a selection pressure for both physical and behavioral formidability (Manson and Wrangham 1991; Wrangham and Peterson 1996).

Physical Formidability, Resource Control, and the Ability to Impose Costs

Given the importance of discerning who is most able to inflict harm upon others, it seems that humans have evolved cognitive capacities for extracting formidability-relevant information from morphological, or nonverbal, signals to dominance (Sell et al. 2009). Some of these signals may be the individual’s physical strength and size (Blaker and Van Vugt 2014), which may indicate to others their perceived aggression and ability to succeed in agonistic encounters (Archer 1988; Gallup et al. 2007). Other visual characteristics, such as masculine facial characteristics (i.e., height-to-width ratio, more prominent feature brow), are believed to be signals of an individual’s dominance (Little and Roberts 2012). These facial characteristics, with links to testosterone, signal an individual’s formidability, fighting ability, and propensity for dominance-related behaviors (Carré et al. 2009; Stirrat et al. 2012). Alongside this, auditory cues may signal an individual’s dominance. Deeper vocal acoustics can convey an individual’s threat potential through its stable relationship with physical strength and size and testosterone (both endogenous and exposure during development) (Bruckert et al. 2006; Feinberg et al. 2005). Expressions of vocal pitch are, however, dynamic, and it seems that those high in dominance are disposed to modulate

their pitch to invoke signals of their formidability, while those lower in rank or dominance reactively modulate their pitch to accommodate their high-dominance counterpart (Cheng et al. 2016). While some evidence indicates that these markers do predict an ability to impose costs on others – and have further been observed to predict an individual's social rank (Keating et al. 1981; Klofstad et al. 2012) – recent evidence suggests that these relationships are likely to be small (Haselhuhn et al. 2015).

Individuals high in dominance may maintain power through a monopoly over resources, be they material or sexual (Mazur 1985). Individuals who are physically formidable, and thus have a greater chance of success during agonistic encounters (Archer 1988), are more able to aggressively control group resources and face fewer costs (Hammerstein and Parker 1982; Petersen et al. 2013). The defensibility of these resources has broad implications for the steepness of social hierarchies. When resources are scarce and certain individuals have disproportionate control, competition and rank asymmetries become heightened (Pierce and White 2006). Low-ranking individuals are likely to acquiesce to the wishes of a physically dominant individual through fear of both physical harm and also of the individual withholding valuable resources (Hawley 1999; Mazur 1985).

However, physical formidability alone is a noisy signal and can also signpost an individual's ability to generate benefits for others (Blaker et al. 2013; Lukaszewski et al. 2016), thus also being an attribute associated with prestige. Physical formidability is a form of embodied capital, whereby the narrower traits that comprise formidability (i.e., muscle mass and height) are biologically costly investments that take a great deal of time and energy to develop (Kaplan et al. 2003). The information conveyed by physical formidability is multidimensional as the development of such traits can improve an individual's hunting and foraging ability (Apicella 2014; Gurven et al. 2006; Jones and Marlowe 2002) and aid in community defense (Van Vugt et al. 2008), alongside cueing an ability to inflict harm. The combination of physical formidability and individual

differences in personality, motivations, and emotional profile that signal an individual's willingness to inflict harm upon others (Cheng et al. 2010) delivers a distinct profile that disposes certain individuals to propagate fear among group members.

Dispositional Dominance and the Willingness to Impose Costs

There are stable individual differences in the psychological profiles that make certain individuals disposed to dominance (Henrich 2016). Individuals high in dispositional dominance are high in a combination of narrower personality traits, having high levels of aggression and extraversion, and dominance being marginally associated with neuroticism (Cheng et al. 2010). Moreover, those high in dominance are also narcissistic self-aggrandizers, and dominance has a negative association with genuine self-esteem and agreeableness (Cheng et al. 2010). This profile is linked with hubristic pride, which is marked by arrogance and conceit, and is further associated with poor mental health, lack of conscientiousness, and an inability to forge and maintain stable, positive relationships (Tracy et al. 2009). However, hubristic pride may have evolved to motivate a willingness to impose costs on others. The related subjective and egocentric ideals of grandiosity and superiority may provoke antisocial behaviors that induce fear among conspecifics, which has reproductive and social benefits that balance the negatively associated outcomes (Ashton-James and Tracy 2012). Furthermore, the combination of these stable traits and egocentric status motivations increases an individual's willingness to inflict costs on others to obtain goals (Sijtsema et al. 2009).

There may be gender differences in cost imposition. Evidence suggests that males are more likely to impose direct costs on others through direct aggression (i.e., imposing physical costs on others), while females are more willing to indirectly aggress (i.e., gossip: Card et al. 2008; Griskevicius et al. 2009). For instance, a key tactic in female mate competition involves spreading

information aimed at maligning the reputation of her romantic rivals (Reynolds et al. 2018), whereas males often focus their efforts on inflicting (or threatening to inflict) costs on rivals and mates in addition to provisioning benefits to the latter (Miner et al. 2009).

The Costs and Benefits of Dominance and Cost Imposition

There is a plethora of individual benefits for high-ranking individuals whose positions are derived from signaling an ability and willingness to impose costs on others. In several small-scale societies, males high in dominance have greater reproductive success (von Rueden and Jaeggi 2016) and achieve positions of considerable influence (Konečná and Urlacher 2017). Experimental evidence has also indicated that males perceived high in dominance are more attractive as short-term mates (Kruger and Fitzgerald 2011). Those high in dominance also have a greater likelihood of becoming leaders and to receive deference and achieve positions of high rank in both formal (Magee and Galinsky 2008) and informal hierarchies (Cheng et al. 2013).

While individuals high in dominance may impose costs on their counterparts, evidence also suggests that groups may, on certain occasions, benefit from the dominant inclinations of certain group members. There are fewer individuals vying for influence in dominance hierarchies, which may ease tensions within a group and facilitate effective coordination (Ronay et al. 2012; von Rueden et al. 2014) and punishment of norm violators (O’Gorman et al. 2009). Individuals high in dominance may also provide group benefits during times of intergroup conflict (Wilson et al. 2001). Such individuals may inflict costs on an out-group, increasing the competitiveness and success of an in-group (Halevy et al. 2008). It is important, however, to note that these group benefits are by-products of those high in dominance creating fear to attain their egocentric goals. Recent evidence indicates that dominance-related social rank does not depend on (mis)perceptions of contributions from high-

dominance individuals (Cheng et al. [in prep](#)). Thus, the benefits that may result in rank relations weighted by dominance are a result of the fear of retribution that subordinate individuals harbor.

Constraining Dominance and Cost Imposition

In many human groups, there are several mechanisms that restrict an individual’s ability to impose costs on group members. Humans are unusual in the ease with which they form cooperative groups and coalitions (Gintis et al. 2015). Coalitional groups can attain a multitude of fitness-enhancing outcomes in comparison to individuals acting in isolation (Price et al. 2002). One such outcome is the ability to coordinate action against those who impose costs on others (the so-called *reverse dominance*, Boehm 2009). Many groups exhibit an aversion toward exploitative dominance-related strategies, and groups members are more likely form alliances (Eibl-Eibesfeldt 2017; Gavrilets 2012), spread negative gossip (Feinberg et al. 2014), dislike (Anderson and Willer 2014), or exit the group when there are available options (Price and Van Vugt 2014) to counter the influence of an individual high in dominance.

Conclusion

The ability and willingness to impose costs on others comprises a dominance profile. The diminished potency of physical and overtly violent cost imposition, and the increased reliance on manipulation (Clutton-Brock 2009) and coercion through psychological fear (Henrich and Gil-White 2001), has distorted dominance relationships, constraining the efficacy of dominance to certain contexts. Such contexts when individuals can impose costs are those where no strong norms sanctioning dominance-related strategies have developed (Pandit and van Schaik 2003); when the structural properties of a group make interactions between subordinates incredibly difficult (i.e., transitive or non-cohesive groups: Pellegrini and Long 2003), in formal hierarchies

(Magee and Galinsky 2008); and when groups have norms that may promote dominance (i.e., in delinquent gangs: Henry et al. 2000; Redhead 2016). Nevertheless, group members may coordinate and, in some cases, effectively develop counter dominance strategies to level the influence of dominant individuals (Boehm 2009).

Definition

Induced ovulation is the phenomenon of females of a species having their ovulation be triggered by the act of coitus.

Introduction

Jöchle (1973) challenged the research at the time that argued that “induced” or “provoked” ovulation did not exist in the human species. According to others, the phenomenon was almost considered mythical, existing only in “old wives tales” with no evidence in the medical literature. Jöchle, however, reviewed the existence of coitus-induced ovulation in several species, where it “synchronizes semen disposition, transport, and capacitation, as well as of ovulation” (p. 523).

Jöchle (1973) reported that induced ovulating species were most likely induced by nervous stimulation of the genital tract, which triggered luteinizing hormone release (luteinizing hormone is the hormone responsible for ovum release or ovulation). However, current research in induced/spontaneously ovulating species shows that not only it is the seminal fluid that induces ovulation but also it is a factor that is a potent stimulator of luteinizing hormone (Adams and Ratto 2013). These Ovulation Induction Factors (OIFs, bioactive pro-hormone forms) are absorbed through the female reproductive tissue into the bloodstream. This process has been documented in rats (Aiyer et al. 1974), Bactrian species (Pan et al. 1992; Chen et al. 1985), alpacas (Sumar 1994), koalas (Johnston et al. 2004), Llamas (Bogle et al. 2011; Silva et al. 2011a; Ratto et al. 2006), cows (Tanco et al. 2012), mice (Bogle et al. 2011), and rabbits (Silva et al. 2011b). It is important to note that many induced ovulation species do not show ovulatory signals (Takahashi et al. 2009).

Ovulation Induction Factors in Humans

Jöchle (1973) argued that coitus induced ovulation occurs in humans as well. In the past 40 years, it has become clear that just as in other species, this may be occurring via seminal plasma. Human semen contains ovulatory hormones, immunosuppressants, pregnancy maintaining compounds, and psychoactive compounds (Burch and Gallup 2006). The following ovulatory hormones are present in human semen: estrone (Ney 1986), estradiol (Luboshitzky et al. 2002; Ney 1986), follicle

stimulating hormone (Ney 1986), luteinizing hormone (Ney 1986), and luteinizing hormone releasing hormone (Chan and Tang 1983). Of these, luteinizing hormone releasing hormone is the most appropriate as an ovulation induction factor, acting in physiologically similar ways to the ovulation induction factors in species listed above. However, human males also have five times more luteinizing hormone in their semen than circulating blood levels (Ney 1986). Other ovulation induction factors may not be needed when luteinizing hormone is in such high levels. Induced ovulation in humans could be due to luteinizing hormone, luteinizing hormone releasing hormone, both, or another ovulation induction factor.

Coitus Induced Menstrual Shifts in Humans

Cutler et al. (1979) first investigated this when seven of the eight women studied who experienced extreme cycle lengths also had sporadic sexual behavior. These same authors in 1980 showed that there were no aberrant short menstrual cycles and relatively fewer cycles that lasted over 33 days among the regular sexually active women. Veith et al. (1983) investigated the effect of exposure to males (sexually or sleeping) to ovulation. Around 92% of the women who spent two or more nights with a male ovulated, as compared to only 56% of the women who only spent one night or less with a male. However, no relationship was found between sex and ovulation. It was suggested that it was not the number of sexual encounters but the consistency that had an effect on ovulation. Given that consistent intercourse was key, it would be very difficult to determine induced ovulation with this methodology.

In 1985, Cutler, Preti, Huggins, Erickson, and Garcia found that women who maintained a weekly coital frequency had a zero incidence of short cycles and very long cycles. Women who reported regular weekly sex with men had a greater incidence of fertile menstrual cycles. Finally, in 1991, Burleson, Gregory, and Trevathan studied the effect of heterosexual activity on menstrual cycle variability. Celibate women had more variable cycles than women having

regular, frequent sex, even when gynecological maturity was controlled for. This is similar to the Whitten effect in rodents where females isolated from males display irregular cycles (Nelson 2011). It is important to note that all studies found that sex had to be consistent to have an effect on the menstrual cycle. The data indicate that unprotected sexual activity influences the female menstrual cycle, thereby indicating the role of seminal compounds.

The Selection Pressure for Ovulation Induction Factors

Various hormones that work in concert to trigger ovulation are found in human semen, and several studies have found an effect of unprotected intercourse on the human menstrual cycle. There is mounting evidence that human seminal fluid can trigger ovulation if women are exposed to it at the appropriate time. The next question is why seminal fluid may have evolved to do this. What is the selection pressure that led to the ovulation induction factors in human semen?

The data indicate that human seminal fluid evolved to counteract the ambiguity of concealed ovulation in humans. Sillén-Tullberg and Moller (1993) concluded that in the majority of instances when ovulatory signs have disappeared, it has been in a non-monogamous context and concealed ovulation is more tightly coupled with monogamy than any other mating system. They also concluded that the absence of ovulatory signs could be an important, though not necessary, prerequisite for the evolution of monogamy if concealed ovulation evolved first. Essentially, concealed ovulation could have been a factor pushing humans into a monogamous mating system.

The most cited hypothesis regarding the evolution and adaptivity of concealed ovulation was put forth by Alexander and Noonan (1979) that females concealed ovulation as a strategy to obtain male aid for females and children. This would be a limiting factor on male reproductive success; time spent investing in partners and children would subtract time and effort spent reproducing with other women. If concealed ovulation forced males into monogamy, it created a selection pressure in human males to develop counter strategies, such as semen chemistry. Males who were better able to

“synchronize semen disposition, transport, and capacitation, as well as of ovulation” as Jöchle (1973) stated, would not have to stay at home with one partner to ensure fertilization. Fertilization would become more efficient, allowing men to reduce investment in a given female partner and move on to another. Moreover, this relationship between concealed ovulation and induced ovulation has been seen in other species (Takahashi et al. 2009). Ovulation induction factors in semen actually appear to be a relatively common response to concealed ovulation.

Conclusion

Induced ovulation appears to be a common male response to female concealed ovulation, made possibly through ovulation induction factors in seminal fluid in several species, and may occur in humans through the same mechanism. Further research is needed in the relationship between concealed ovulation and induced ovulation across species, and exactly how and how often induced ovulation occurs in humans.

Definition

Terminating investment in an offspring by abandoning the offspring.

Introduction

It has been well established that parenting is a complex behavior. Parental investment theory posits that this complexity is partially due to the lack of resources in the environment and the high cost of parental investment (e.g., physical energy during gestation, breastfeeding, and postnatal protection of the offspring; Trivers 1972). These factors may collectively compel parents to (both consciously and unconsciously) make harsh decisions about whether it may be more beneficial to invest in themselves or in their offspring. Evolutionary theory suggests that it may indeed be favorable for parents to, under certain circumstances, terminate investment in a given offspring to either (a) invest more in the other more viable offspring or (b) invest in the parents' own growth and development so that they may have more viable offspring in the future. In any case, parents may be susceptible to reducing investment in their offspring in the context of a less favorable environment. One such case is infant abandonment.

Infant abandonment is the practice of completely terminating parental investment in an offspring with the intent of never again providing care for the offspring (Maestripieri and Carroll 1998). Although it may be considered to be a form of child abuse or neglect, it appears that infant abandonment may be one example of characteristically “maladaptive” parental behavior that may provide adaptive benefits under certain environmental conditions. This is because infant abandonment, unlike other forms of child abuse or neglect, results in immediate termination of parental investment and costs associated with parental care (Maestripieri and Carroll 1998). This suggests that infant abandonment may indeed be a parental, and more specifically maternal, adaptation in an unfavorable environment that limits parental care.

Infant Abandonment as a Maternal Adaptation

Parenting decisions, including decisions to invest in or abandon the infant, are especially pertinent for mothers compared to fathers. This may be due to a number of important evolutionary differences between paternal care and maternal care. First, in accordance with Bateman's principle (1948), the larger gamete size and reduced availability of gametes in females, as compared to males, suggests that the reproductive strategy should differ in women and men. Specifically, because the production of an ovum is more somatically costly, women should pursue a reproductive strategy that emphasizes selectiveness whereas males can afford a relatively less restrictive sexual strategy as sperm is minimally costly and more readily available. Second, partially due to these reasons, females typically have a lower reproductive variance compared to males and therefore should be more selective of their parental investments in especially lower quality offspring compared to males (Dawkins 1976). Third, because mothers give birth to the offspring and are therefore already have invested quite a bit in the offspring compared to males, in conjunction with also being the primary source of nutrition for the offspring (e.g., breastfeeding in mammals; Hrdy 1999), infants across species are almost entirely dependent on their mothers to provide warmth, nurturance, protection, and other resources (Hrdy 1992).

However, as previously discussed, in certain adverse environments, the resource requirements of an offspring may be greater than the resources a mother is able to provide. For example, breastfeeding in some smaller species (e.g., rats) is sometimes metabolically more expensive than pregnancy itself and has the potential to deplete a mother's fat stores and jeopardize her health (Prentice and Prentice 1998). Therefore, a "greedy freeloader" baby who is less viable and in need of more sustenance may put an extra strain on a mother's resources (Hrdy 1999). To illustrate, baboon mothers who carry their unweaned infants are twice as likely to die, and half of the unweaned baboon infants will die, within the first two years

of life due to the energetic and physical costs associated with providing care for an offspring and themselves. As such, both parties are faced with an adaptive challenge (Hrdy 1999). This example demonstrates that it may sometimes be beneficial for a mother to forgo investment in a present offspring for later investment in a more viable offspring when more resources are available. Consequently, rejecting an offspring could mean increased resources for her, a chance at finding better quality mates, and an opportunity to invest more in a future offspring that may be more viable, all of which lead to increased evolutionary fitness for the mother.

Infant Abandonment in Humans

Therefore, cases of infant abandonment (mostly by the mother) are found across species, including humans. Historical records suggest that parents in medieval Europe abandoned their infants with the presumption that the child may be raised by another caregiver who is better able to provide for the child (e.g., the tale of Romulus and Remus being raised by a mother wolf; Hrdy 1992). Indeed, between the antiquity and the renaissance in Europe, it was common for couples without children to care for abandoned infants. Some of the abandoned infants were not claimed by anyone and would subsequently die; however, parents would still choose to abandon them knowing that this was a possible outcome (Hrdy 1999). Cases of infant abandonment still occur today. For example, it is common practice for mothers in economically poor areas of northeast Brazil to abandon their newborns, especially when the infants show cues of low survivability (Scheper-Hughes 1984). A common example of a more socially acceptable form of abandonment that is prevalent in both developed and developing countries is putting a child up for adoption (Hrdy 1992).

Potential Factors Associated with Infant Abandonment

Examining the patterns of infant abandonment across species, including nonhuman and human

animals, provides some insights into some of the important factors associated with such behavior.

Environmental Factors

Environmental factors appear to be a consistent correlate of infant abandonment across species. In nonhuman animals, extreme environmental scarcity/adversity and intra-sexual competition, especially for lower ranking females, are strong predictors, as such contexts will likely result in lower resource availability for both lower-ranking females and their offspring to survive on (Hrdy 1979). Similar environmental factors along with lower levels of social support appear to be important for infant abandonment in humans. For example, among Malaysian mothers, being unemployed, having unemployed partners, and having a rape-related pregnancies were all risk factors for infant abandonment (Suan et al. 2018). Additionally, mothers who were observed to abandon their infants in Kazakhstan had less stable incomes and were single mothers, compared to mothers who did not abandon their infants (Yelissinova et al. 2015). Although extreme environmental adversity alone is shown to sometimes be sufficient for parents to make the decision to abandon the infant, other factors may also play a role.

Child Characteristics

Another important factor associated with infant abandonment is the infant's health. A less healthy child may deplete parents' resources and limit the propagation of parents' genes (Volk and Atkinson 2008). Therefore, parents may be predisposed to prefer and invest more in offspring that exhibit cues of high health (Volk and Quinsey 2002). Indeed, various nonhuman animals are observed to terminate investment in offspring that appear to be weak or low in health (Mappes et al. 1997). Similar findings are also seen in humans' caregiving perceptions as well as their actual behavior and investment decisions toward less healthy, or even less healthy-looking, infants and children (see Franklin and Volk 2018 for a review).

Additionally, the child's age may also influence abandonment decisions. Most infants in the ancestral environment failed to survive through their first year of life (Volk and Atkinson 2008).

This is also the case, albeit to a lesser degree, in modern environments. Newborns are more likely to die due to infections, diseases, and lower quality care compared to older infants (Voora et al. 1982). For these reasons, parents may be inclined towards investing in older infants (Franklin et al. 2018). Moreover, terminating investment in an offspring may be easier if it occurs relatively early, as opposed to later, in the offspring's life. For example, infant abandonment in fish, known as brood desertion, occurs under conditions of food deprivation early in the breeding season when parents have not yet put in much investment in their eggs (Maestripieri and Carroll 1998). Similarly, marsupial mothers are especially prone to abandoning their infant presumably due to their relatively low-investment gestation that favors relatively easy and low-cost abandonment (Wasser and Barash 1983). Even in humans, abandonment is more likely to occur at the newborn stage, as seen in Kazakhstan (Yelissinova et al. 2015) and northeast Brazil (Scheper-Hughes 1984). These findings suggest that parents may be less emotionally attached to younger offspring due to less time spent with the offspring and the costlier investment in newborns due to their lower chance of survival (Bowlby 1980; Franklin et al. 2018).

Parent Characteristics

There are also patterns of some parental characteristics associated with cases of infant abandonment. Studies show that infant abandonment may be more prevalent among younger females across species, including humans (Wasser and Barash 1983). A study that examined the characteristics of infant abandonment among unmarried mothers in Malaysia suggested that being a first-time mother and being a younger mother were important correlates. Similarly, Yelissinova et al. (2015) compared a cohort of 17 mothers who gave up their babies in a maternity hospital in Kazakhstan to a cohort of mothers from the same hospital who did not choose to give up their babies. The results suggested that the women who gave up their babies were more likely to be teenagers. Additionally, Kim (2017) conducted a media report analysis that examined stories of newborn

abandonment in South Korea from 2011 to 2016. The mothers of these infants were usually young women in their 20s. Younger mothers are more likely to abandon their infants compared to older mothers likely because younger mothers have more opportunities to have offspring in the future (Maestripieri and Carroll 1998). Younger mothers may also lack the emotional regulation and resources that older mothers may have and therefore, may have negative attitudes towards parenting, demonstrate less responsiveness towards their infant, and engage verbally with their infant less often (see Belsky 1984 for review).

Additionally, individual differences, such as personality traits, may contribute to harsh parenting decisions including infant abandonment. Studies have found that personality traits, such as lower levels of Honesty-Humility (tendency to exploit others; Lee and Ashton 2004), Emotionality (tendency to feel attached toward kin; Lee and Ashton 2004), and Agreeableness (tendency for willingness to be exploited; Lee and Ashton 2004) on the HEXACO Personality Inventory are associated with negative perceptions and lower hypothetical investment toward infants, especially toward newborns (Franklin and Volk 2018). Moreover, higher levels of Neuroticism (tendency to experience negative emotions, such as anger, anxiety, and worry; Jeronimus et al. 2014) on the Big Five Personality Model is shown to be associated with rejecting behaviors toward children (Kochanska et al. 1997). These traits may have evolved as an adaptation to adverse environmental contexts (Buss and Greiling 1999). With regards to parenting behaviors such as infant abandonment, more specifically certain callous and less prosocial personality traits, such as the ones discussed in this section, may have served an adaptive purpose to help parents make harsh parenting decisions, such as terminating investment in an infant, when necessary.

Finally, mothers' psychological well-being that arises from their developmental histories is also shown to be an important factor associated with the infant abandonment. Mental illnesses, such as anxiety, panic disorders, attachment disorders, and postpartum mood disorders, have been suggested to impair the capacity for parenting and

increase the likelihood of infant abandonment (Megahead and Cesario 2008). These seemingly maladaptive disorders and illnesses may in fact have evolutionary benefits for parents by triggering certain parenting behaviors, when environmental pressures may not support a parents' investment in an offspring. An important example of this is Postpartum Depression (PPD).

Postpartum Depression

PPD is an affective disorder that affects are in seven women after giving birth, that is characterized by a period of emotional disturbance and depression that interferes with the developing bond between mother and child and detracts the pleasure of motherhood from the afflicted woman (APA; Stuart and O'Hara 1995). Symptoms of PPD include tearfulness, dependency, mood lability, feelings of guilt and inadequacy, disturbances in appetite and sleep, excessive worry about the health of the infant, subjective evaluation of themselves as "bad" mothers, and suicidal ideation (Stewart 2005). PPD is strongly associated with the lack of social support, life stress, reduced marital relationship quality, and other stressful life events (Beck 2001; Belsky 1984; O'Hara and Swain 1990).

The gestational and following postpartum periods are a time of rapid hormone fluctuation and cognitive change designed to prepare the mother for her new role as caregiver, regardless of how favorable her current environment may be. Specifically, Hagen (1999) proposes that postpartum affective disorders, such as PPD, may be adaptations that compensate for costs associated with gestation and parenting by informing the mother that she has suffered a social injury, or a "fitness loss." This may motivate her to reduce reproductive costs by reducing parental investment.

Conclusion

Infant abandonment is undoubtedly a heavily stigmatized behavior. However, evolutionary theory provides some insight into why some parents throughout history may feel as though abandoning their infant may be their only option. More specifically, evolutionary theory not only provides an

important framework for understanding the underpinnings for such decisions but also provides insights into the ways in which we can reduce these incidences. While infant abandonment is by no means a desirable decision, even the most developed societies lack adequate resources for supporting parents and reducing such behavior. For example, we know that harsh environments, such as economic hardship, across cultures may be an important and consistent predictor of infant abandonment. Thus, it may be beneficial for parenting interventions to provide support and services for parents such as providing family planning resources, access to abortion, and subsidized family counselling as these parents may be more at-risk for abandoning their infants and making other harsh parenting decisions (Hrды 1999).

Definition

Human infants are very vulnerable and dependent on their caregivers for survival into reproductive age. The attachment system, as defined by John Bowlby, is a behavioral control system with a set goal of maintaining proximity to caregivers, which has been retained through evolution as it increased the chances of survival against predators and other natural dangers (i.e., the functional consequence). Bowlby also argued that caregivers have a complementary caregiving system making

them responsive to children's attachment behaviors. Thus, although children (the weaker part) attach to their caregiver(s) (the stronger part), and not the other way around, children's forming of attachment is a collaborative effort. Mary Ainsworth subsequently discovered three organized patterns of attachment (i.e., secure, insecure-avoidant, and insecure-ambivalent/resistant), which have all been argued to be evolutionarily adaptive in that they enable children to adapt to their particular local environments and thereby increase chances of survival.

Introduction

Human children are born very vulnerable and are thus dependent on their caregiver(s) support in order to survive into reproductive age. Indeed, the proportional amount of time that human children are dependent on their caregivers is largely unparalleled in other species. Behavior systems enabling children to take an active part in affecting their caregiver's caregiving behaviors therefore constitute an evolutionary advantage. Universally, human infants are also seen to form strong bonds – attachments – to their caregivers, seeking to maintain proximity to and protesting separations from their caregivers and using them as a reference point, a secure base, from which to explore the environment. John Bowlby, a child psychiatrist and psychoanalyst, sought to understand the nature of children's ties – attachments – to their caregivers; why do children form attachments to their caregivers, and what is the function of attachment? The specific function of attachment according to Bowlby – increasing chances of survival by means of proximity to caregivers – is discussed below.

Infant Survival by Means of Maintaining Proximity to Caregivers

Bowlby could not accept the theories of attachment available at the time, since they deemed attachment secondary to processes such as feeding and/or other motivational processes (i.e.,

drives). Bowlby (1997/1982) deemed these theories unscientific and contrary to evidence and therefore sought an alternative explanation for attachment as a primary motivation in itself (see ► [“Psychodynamic Foundations”](#)). He came to draw from multiple sources, including his own experiences working as a child therapist, clinical research he had done on children with externalizing behavior problems (e.g., Bowlby 1944), scientific collaborations in which he examined effects of early child-caregiver separations (e.g., Robertson and Bowlby 1952), and research and theory from multiple scientific disciplines (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)).

Bowlby became particularly influenced by ethology, cybernetics, and cognitive psychology (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). Bowlby argued, following Darwin (1859) and the theory of natural selection, that humans (like all other animals) should be endowed with behavioral systems that whence evolved have been retained in evolution because they have been associated with adaptive functions in our ancestral species-typical environments. He consequently argued that we must search for an adaptive function of attachment in our environment(s) of evolutionary adaptedness (EEA), which have provided the pertinent selection pressures for an attachment behavioral system to develop. With the words of Bowlby, “Just as Darwin found it impossible to understand the structure of an orchid flower until he knew what insects flourished and visited it. . . , so, it is held, it is impossible to understand man’s instinctive behavior until we know something of the environment in which it evolved” (Bowlby 1997/1982, p. 61). Bowlby argued that ethology was the best present-day application of Darwin’s theories to behavioral systems in animals, drew heavily from ethology, and argued that the human attachment system should have prototypes in other animals. Bowlby also found that imprinting in birds and attachment behavior in other primates bear notable similarities to attachment behaviors in human children, which he argued may stem from convergent selection pressures as other animals have faced the same survival-related threats from

predators (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)).

More specifically, Bowlby argued that the attachment system must have been retained due to it serving the specific function of increasing the chances of survival. Bowlby argued that in humans’ primeval environment and ecological niche, humans were living as nomads in small hunter-gatherer societies, in environments comparable to that of other large ground-living species of higher primates. A key characteristic of our ancestral environments, according to Bowlby, was a risk of falling prey to predators and other natural dangers. Thus, he argued a behavioral system that monitors the whereabouts of and promotes the maintenance of proximity to caregiver (s) should have served an important function that increased the chances of survival. Indeed, Bowlby argued that proximity to caregivers is the predictable outcome of activation of the attachment system, which has served an adaptive function in reducing the risk of falling victim to predators and other natural dangers (i.e., the functional consequence); “Because immature organisms are usually very vulnerable they are commonly endowed with behavioral equipment that produces behaviors specifically likely to minimize risk, e.g. behavior that maintains proximity to a parent” (Bowlby 1997/ 1982, p. 143).

Children are thought to be endowed with attachment behaviors and prepared to form attachments to caregivers who are continuously present and responding to their signals. Attachment behaviors, which are triggered by internal (e.g., sickness, pain) and external (e.g., separations from caregiver, strangers) cues of danger, include all behaviors that children use to maintain and increase proximity to their caregivers, and they are thus defined by their function, with increasing development expanding the repertoire (see ► [“Individual Variations in Attachment”](#)). Attachment behaviors are often grouped into three broad classes of behaviors: aversive signaling behaviors (e.g., crying, screaming), positive signaling behaviors (e.g., smiling, vocalizing), and active behaviors (e.g., following, clinging). Terminating signals, which decreases the activation of the attachment system, includes signals conveying

that there is no more cause of alarm. For young children this typically pertains to close physical proximity to the caregiver whereas older children can often be soothed by other means. Importantly, children's attachment relationships are hierarchical; children (the smaller, weaker part) form attachments to their caregivers (the stronger, wiser part), not the other way around. Bowlby however also argued that caregivers are endowed with a caregiving system that typically makes them biased and responsive toward their children's signals, for example, retrieving children following signs of danger. Children's forming of attachment is therefore a collaborative effort.

Bowlby's close collaborator Mary Ainsworth (Ainsworth et al. 1978) and Mary Main (Main and Solomon 1986) subsequently discovered specific categories of individual variations in attachment security and organization, corresponding to particular patterns of caregiver sensitivity in relation to their children's signals (see ► [“Individual Variations in Attachment”](#)). These categories are (currently) secure attachment (see ► [“Secure Attachment”](#)), insecure-avoidant attachment and insecure-ambivalent/resistant attachment (see ► [“Organized-Insecure Attachment”](#)), and disorganized attachment (see ► [“Disorganized Attachment and Reactive Attachment Disorder”](#)). From a developmental psychology perspective, secure attachment is typically regarded as the optimal way of organizing one's attachment behaviors, with the insecure patterns judged suboptimal due to their links to increased risk for maladaptive development (see ► [“Effects of Attachment Quality and Organization”](#)). All three organized patterns of attachment (i.e., secure, insecure-avoidant, insecure-resistant/ambivalent) have however been discussed in evolutionary terms as adaptive ways of organizing attachment behaviors so as to maintain as much proximity as possible in relation to the caregiver(s) and thereby aiding survival, with no organized pattern of attachment inherently superior to any other one (Main 1981; Simpson and Belsky 2008). Indeed, Bowlby argued that the attachment behavioral system is open to learning so as to function adaptively in children's particular environments. Avoidant attachment (minimizing expressions of

vulnerability in relation to a caregiver that has previously rebuffed the child's bids for proximity) may thus constitute an adaptive way of ensuring some level of proximity to the caregiver without risking further rejection and potential abandonment. Similarly, ambivalent/resistant attachment (showing high levels of negative affect and maximizing attention toward a caregiver that has previously been inconsistently sensitive) may constitute an adaptive strategy for not being overlooked in the presence of danger.

Bowlby was very specific that the set goal of attachment is the maintenance of proximity to caregivers due to caregiver proximity facilitating protection against predators (and other natural dangers). Bowlby discarded a hypothesis that attachment facilitates learning skills necessary for survival from caregivers with the argument that the biological function of a behavioral system cannot be any favorable outcome its performance may have; “Biological function is defined more narrowly: it is that consequence that in course of evolution has led the behavior in question to become incorporated into the biological equipment of a species” (Bowlby 1997/1982, p.224). Hence, he argued that a specific advantage in terms of survival and reproduction must be conferred by the behavior, leading the individuals who display it to achieve higher rates of survival and reproduction (i.e., leaving more progeny). As rhetorically asked by Bowlby (1997/1982): if attachment serves a function of facilitating learning, why does attachment persist into adulthood, when critical learning is complete? (see also ► [“Attachment in Adulthood”](#)).

In support of his argument, Bowlby noted that observations of many species of animals indicate that an isolated animal is more likely to be attacked by predators. Attachment behaviors are moreover elicited particularly easily in animals which “by reason of age, size, or condition, are especially vulnerable to predators, for example the young, pregnant females, the sick” (1997/1982, p.226). Attachment behaviors also tend to always be elicited at high intensity when an animal is alarmed (e.g., in danger). Bowlby also noted that the finding that young offspring attach even to caregivers who are hurtful and

frightening to the offspring is hard to explain by any other theory.

In a possible critique of Bowlby's position, he also argued, however, that variations in the quality of children's attachments to their caregivers are of substantial importance for their personality development. He argued that children construct cognitive-affective internal working models (IWMs) from attachment-related experiences with the caregiver(s) that whence constructed will influence perceptions and expectations of the self and others and thereby how we will behave in relation to others (Bowlby 1997/1982). Although this may be regarded as a secondary side effect of variations in attachment security and organization, not a primary functional consequence in itself, it does raise the possibility that attachment has functions beyond immediate survival against predators, such as learning skills to function adaptively in one's broader social group. Indeed, Main and Hesse (1992) argue that the attachment behavioral system likely serves multiple survival functions, including protection from unfavorable temperature changes and attacks by conspecifics. Relatedly, although Bowlby was right in arguing that attachment is not secondary to feeding, proximity to caregivers also increases chances of getting fed as well as learning what is edible (Harlow and Zimmerman 1959). Current research is also examining the importance of attachment for adult functioning, such as for reproductive strategies, with some findings indicating that attachment security and organization may affect onset of puberty (Simpson and Belsky 2008).

Conclusion

Children's attachments and attachment behaviors are the result of an attachment behavioral control system that continuously monitors the whereabouts of the caregiver(s) and has the maintenance of proximity to caregivers as a set goal. This system, which bears similarities to imprinting in birds and attachment in other primates, has been retained in evolution as it, according to Bowlby, has served a specific function of increasing

survival against predators and other natural dangers. The attachment system is moderately open to learning, and children develop different patterns of attachment in relation to their caregivers depending on the caregiver's pattern of responding to the child's signals, with all organized patterns argued to be evolutionarily adaptive in maintaining proximity to the caregiver in children's specific environments.

Introduction

From humanity's distant past, there has existed a range of archetypal narratives relating to the

murderous actions and intent of parents toward their children, whether they be biological offspring or adopted. The Hebrew God, for example, tested Abraham by ordering him to sacrifice his son Isaac. The Greek myths of Oedipus Rex, Medea, and many fairy tales from a range of different times and places reflect the enduring and cross-cultural expression of this aspect of human behavior over millennia.

Infanticide has often been used as a generic term to refer to this complex phenomenon. However, it has had different meanings depending on time and context. In Biblical times, the term infanticide included any young children murdered by either parent or the State. The modern medicolegal interpretation of the term infanticide is, in contrast, more restrictive.

Although infanticide legislation varies cross-nationally, it only includes certain mothers who kill their young children while considered to have been under the adverse effects of giving birth when they killed. However, for research purposes, the generic term “infanticide” is too broad to reflect the heterogeneous patterns in the way parents have killed their children. An expanded classification taxonomy is thus used to identify specific subtypes of parental child killing as part of this complex phenomenon.

Definitions

The term neonaticide refers specifically to the killing of an infant at birth born within the first 24 h of life (Resnick 1970). The term infanticide is most commonly used to mean the killing of an infant during the first year of life (Friedman et al. 2005). The term filicide is used in relation to the killing of any other child under the age of 18 by either parent (Friedman and Resnick 2007).

Without medicolegal constraints in definition, there has been a proliferation of academic literature in recent decades seeking to understand both epidemiological and typological aspects of parental child killing. Different patterns have been identified depending on the age and gender of the child and the parent, and the nature of the parent-child relationship (whether biological or step-parental).

Furthermore, differences in parental motives, stressors, and rates of mental illness have also been identified.

However, until recently there had been no unifying theoretical framework to assist in this area of academic research. Evolutionary social psychology has begun to provide such a heuristic theoretical framework for a range of social and biological sciences. The application of contemporary evolutionary theory to the broad field of study relating to parental child killing provides unique perspectives into this ancient aspect of human behavior that may assist academics, policy makers, and clinicians alike to further inform their respective disciplines and practice.

Infanticide Law

Infanticide laws exist in approximately two dozen nations. The British Infanticide Act allows for charge akin to manslaughter (rather than murder) for mothers who kill their infant while suffering from a mental disorder. It is based on the 1920s beliefs about delivery and lactation hormonally affecting such women to the extent that “the balance of her mind is disturbed by reason of her not having fully recovered from the effect of giving birth.”

Most international laws have followed the British tradition, significantly decreasing the sentence for women who kill their infant. Nations with infanticide legislation include Australia, Austria, Brazil, Canada, Colombia, Finland, Germany, Greece, Hong Kong, Italy, Japan, Korea, New Zealand, Norway, the Philippines, Sweden, Switzerland, Turkey, and the United Kingdom (Friedman and Resnick 2007). In New Zealand, the penalty is decreased for mothers who kill their child up to age 10 and infanticide can be either a charge or a defense. Despite such variances, international infanticide legislation is invariably limited to mothers and remains legally based on very narrow criteria.

Despite their shaky and often unscientific foundation, these Acts were meant to extend compassion rather than punishment to those struggling mothers – indicating societal acknowledgment of

the point whereby a woman could not be held culpable for killing her children under certain circumstances (Friedman et al. 2012a).

However, many women who successfully utilize the defense of infanticide do not suffer from enduring mental illnesses per se. Somewhat ironically, other mothers who are severely mentally ill and kill older children while psychotic would be unlikely to qualify for the defense in most nations. In medicolegal terms, they would be similarly treated to fathers who were mentally unwell at the time of killing their child.

The state then has not relinquished its influence in determining how society interprets and applies the law in relation to parents who kill their children. Nor has the state completely shed the vestige of its ancient role in sanctioning the termination of unwanted children.

Patterns in Neonaticide (Murder in the First Day of Life)

Dating back to at least ancient Greece, when human infants were deformed or weak, they would be abandoned to die from the elements, if not more actively killed (West et al. 2009). Early philosophers including Plato and Aristotle believed that the Greek custom of killing, or leaving to die, deformed or weak infants preserved the population’s integrity (West et al. 2009). Implicit in this custom was the view that a deformed child was somehow an undesirable burden on either the parent or the society.

However, a child’s anatomical traits need not be the only factor determining a parent’s perception of the “undesirability” of the child. Patterns of neonaticide are distinct in the developed world verses the developing world, for example, suggesting different cultural and social influences (Friedman et al. 2012a).

In Japan, for example, there were two types of neonaticide with different terms to describe them (Sakuta and Saito 1981). Japanese cases of *anomie* are similar to neonaticide in the rest of the developed world. In *mabiki*, translating to “thinning out,” the parent or parents kill the newborn because they lack the financial ability to care for

the baby. Similarly, sex-selective neonaticides occur in some countries where a female infant is seen as a liability.

By definition, neonaticides are committed at birth or within the first day of life and the perpetrator is therefore usually the mother acting alone. The infant's biological father is quite often not a part of the woman's life by the time of delivery or, if he has remained in the relationship, the man often does not know of the woman's pregnancy (Friedman and Resnick 2009). Only very rarely is the father known, present, and assisting with the murder.

Most typically, the mother is a young woman, often in her teens or early 20s, who is afraid of the repercussions of both her pregnancy and the infant's existence. This may be due to external pressures such as religious or cultural taboos, extramarital paternity, or unmarried status. Pregnancies and deliveries are often hidden, and both psychological denial of pregnancy and deliberate concealment of pregnancy are common (Friedman and Resnick 2009).

Denial or concealment of pregnancy usually precedes the neonaticide, and both may interfere with the acknowledgment of pregnancy, without which there may be little or no maternal bonding with the pregnancy and the young baby. In concealment of pregnancy, the woman knows that she is pregnant but hides it from others. In affective denial of pregnancy, women do not acknowledge their pregnancy emotionally but may be cognitively aware. In pervasive denial of pregnancy, the woman is not aware that she is pregnant. She may not experience physical signs or symptoms of pregnancy and does not realize she will give birth (Friedman et al. 2007; Miller 2003).

In psychotic denial, the woman by definition has a psychotic illness (like schizophrenia or bipolar disorder) and may intermittently deny her pregnancy. However, mothers with severe mental illness are uncommon in cases of neonaticide. Nor is neonaticide commonly associated with suicide. In fact, young mothers who kill at birth or in the first day of life are much less likely to have mental illness or to commit suicide compared to older mothers who kill their older children (Friedman et al. 2012b).

Patterns in Infanticide (Murder in the First Year of Life)

Infanticides when taken outside of a medicolegal definition form only a subset of parental child killing. Studies of child murder in the first year of life have found that these parents often have multiple life stressors. Economic stress, unemployment, and young parent perpetrators are commonly occurring factors (Friedman et al. 2005).

Many deaths in this age group occur after a period of sustained and chronic child abuse rather than a single homicidal act. Crying children are sometimes believed to be a final precipitant for the parent (disenfranchised and with poor coping and parenting skills) to inflict lethal violence on the child. These victims may be more likely to have physical anomalies. Mothers who kill infants in this age group have variable rates of depression, substance use disorders, or other psychiatric disorders.

Patterns in Filicide (Murder Up to Age 18)

Maternal Filicides

Mothers who kill their children have typically been victims of violence themselves. They have multiple life stressors and are often socially isolated, poor, and the child's primary caregiver (Friedman et al. 2005). Over one-third of maternal filicides happen either while the mother is pregnant with another child or during the first-year postpartum (Friedman and Resnick 2007). Chronic abuse or neglect, substance abuse, and mental illness are not uncommon among these mothers (Friedman and Resnick 2007).

Among the women who purposefully killed their child and who suffered from mental illness, suicide attempts were not uncommon. Some 16–29% of maternal filicides do end in suicide (Nock and Marzuk 1999).

Mothers who do commit filicide - suicide often kill children who are older; these mothers would be unlikely to have qualified for the age range required for an infanticide defense had they survived. In contrast to fathers, mothers are more

likely to only kill their biological child, and possibly themselves, but not their partner.

Paternal Filicides

Less research exists regarding fathers who kill their children. However, they are more likely to be incarcerated than to be psychiatrically hospitalized after their child's murder. Chronic abuse, mental illness, and revenge were, similar to that for the mothers, common themes (West et al. 2009). Approximately one-fifth of children killed by fathers were infants (West et al. 2009).

Studies have indicated that fathers who kill were often under significant financial stress, relationship stress (including separation or looming divorce), and had limited supports (West et al. 2009). Precipitants to paternal filicide included: domestic disputes, anger and rage, abuse or neglect, punishment for misperceived child behavior, revenge, and mental illness (West et al. 2009).

Fathers who kill their children are more likely to commit suicide after their act than mothers (Nock and Marzuk 1999). Fathers who kill their children are also more likely to kill their partner in the same act. When the father kills the whole family, in an act of familicide, Wilson and colleagues described two categories. Angry men killed because of hostility toward their wife whereas depressed men killed to save their families, having nihilistic beliefs of saving them from a fate worse than death (Wilson et al. 1995).

Filicide by Step-Parents

Step-parents kill step-children at much higher rates than biological parents kill biological children. Step-fathers rather than step-mothers are often thought to be the more common perpetrators. However, this is likely related to the percentage of children who live with step-fathers rather than step-mothers rather than a true base rate. In times past, when there were higher maternity mortality rates, many more step-mothers lived with step-children.

Motives

The motives for child murder by a parent tend to fall into one of five categories, initially described

by Resnick (1969). These motives include: most commonly (1) *fatal maltreatment*; less commonly (2) *partner revenge*; (3) *unwanted child*; (4) *altruistic*; and (5) *acutely psychotic*.

Fatal maltreatment was initially termed “accidental” because the death in these cases is usually not anticipated specifically – but instead is the cumulative effect of chronic abuse or chronic neglect by the parent (Friedman and Resnick 2007).

Partner revenge, also known as spousal revenge or Medea syndrome (after the mythical Medea who killed her children to punish her cheating husband Jason), occurs in the context of a divorce or a breakup when one parent kills the child in order to emotionally wound the other parent. (If only one of the children is killed, it will be the other parent's favorite child.)

In *unwanted child* cases, the murder occurs because the parent, rather than seeing their child as a person, sees the child as a hindrance to their own goals. In neonaticides, the infant is often murdered right at birth because they are *unwanted*. It has been suggested that these cases may sometimes represent a delayed effort by the mother to terminate the pregnancy.

The final two motives – *altruistic* and *acutely psychotic* – are usually associated with parental mental illness. In *altruistic* filicide, the parent holds a belief, cognitive distortion, or frank delusion that the child's death is in that child's best interest. This could include when a child/infant was seriously medically ill and the parent believed it was a mercy-killing similar to euthanasia. Alternately, when the parent was severely depressed and planning suicide, they may not wish to leave their child alone in the world. A parent who was psychotically delusional may also hold a nihilistic delusion that a fate worse than death was awaiting their child. In contrast, in an *acutely psychotic* filicide, when the parent is suffering an episode of acute psychosis or mania and kills their child, there may be no comprehensible motive or explanation.

Evolution and Infanticide

Darwin first published *The Origin of the Species* in 1859 and proposed a theory of evolution of

species by a process of natural selection. Through the accumulation of minor trait mutations over millennia, some individuals will be able to better compete for reproductive resources to favor the genetic proliferation of their own offspring and those traits. The so-called “survival of the fittest” of those interspecies rivals is thus assured.

Although contemporary evolutionary theory has advanced considerably in recent times, the five central tenants of Darwinian theory remain at its core: that there is variation in every population; individuals within the population compete for limited resources; more offspring are produced than can survive; individuals pass genetic traits to their offspring; and those with the most adaptive traits are more likely to survive and reproduce.

Early evolutionary scholars were limited to studying the anatomical and behavioral expressions of these traits without fully understanding how they were transmitted. They did, however, understand that aggression, violence, and lethal violence toward offspring was prevalent in nature and sought to understand how killing one's offspring could be an adaptive strategy for an organism to pass on its genes.

Parental investment theory (Fisher 1930) noted that the 1:1 sex ratio of human offspring was an evolutionarily stable gender ratio, suggesting and hypothesizing that parents should be equally invested in their children. However, Trivers' (1974) theory of a parent-child conflict focused upon the extent of the “investment” of the parental resource as being a function of gender, genetic relatedness, and the degree of benefit to the parent in relation to the child successfully having more offspring.

In the case of social animals who often rely upon one another for survival, Hamilton (1964) proposed an arithmetic algorithm to explain an evolutionary basis to altruistic behavior. Hamilton's Rule, $rB > C$ stated that altruism could arise as an adaptive evolutionary strategy when the genetic relationship of the recipient (r) multiplied by the benefit to the receiver (B) is greater the cost (C) to the beneficent party.

The killing of unrelated infants is particularly common among many animals and would in evolutionary terms, seem to make sense. Indeed,

when males commit infanticide in nature, therefore, they primarily kill infants who are unrelated to them, most likely to secure new potential mating opportunities for their own offspring (Liddle et al. 2012).

For example, in pride of lions, when a new lion comes into power, he kills other males' cubs and thus subsequent new cubs are his biological offspring. In mammals, females are often infertile while lactating such that the death of the infant leads the mother to new fertility and subsequently new genetically related progeny for the father (Liddle et al. 2012).

In humans, fairy tales like Hansel and Gretel, Snow White, and Cinderella have also warned for centuries about the dangers posed to children by evil step-parents. Step-parents do not have a biological vested interest in maintaining the unrelated child's genetic material when compared to the significant investment of time and effort in step-parenting.

When females kill the infants of other females, it may instead be in order to secure additional resources for herself and her own offspring, and has been observed in a range of species from squirrels and birds, to monkeys and chimpanzees (Liddle et al. 2012). However, when females kill their own offspring, this too may confer an adaptive advantage in some circumstances due to the disproportionate investment of reproductive resources for females.

Females have limited numbers of eggs and fewer opportunities to reproduce compared to males and their ability to sire multiple offspring. There are also high physiological risks and other costs to the mother in carrying the pregnancy, giving birth, and feeding the offspring. Not paying this investment can be an advantage to the female when resources are sparse. For example, when a young primate is born in the wrong season or is defective which would require extra parental effort, they may be killed to enable the mother a better chance to raise another healthy offspring to reproductive age (Hrdy 1979).

Advances in understanding the anatomy and neurophysiology of the brain throughout the twentieth century enabled a more sophisticated understanding of these complex behaviors.

Behavioral psychologists, ethologists, sociobiologists, and primatologists have described any number of animal models based largely on the limbic system (and its interactions with the forebrain and hindbrain), to identify and explain evolutionary remnants of complex behavior in our own species, including parental child killing.

Animal studies of the genetic inheritance of certain innate instincts, the capacity for emotional expression, language, and variably complex motivational patterns of behavior have all been presented as analogous to parts of the evolved human behavioral repertoire. However, it has been only recently that these behaviors have been seen as responses to inherited cognitive mechanisms from our distant evolutionary past.

Evolutionary psychology proposes human beings have evolved specific cognitive programs, with neurophysiological substrates, to enable us to process significant species-specific environmental stimuli. Attending to and processing that information in an evolutionarily adaptive and stable way has resulted in predictable behavioral responses in our species. However, the behavioral responses need only to have been adaptive to distal evolutionary selection pressures and not necessarily adaptive in a proximal and contemporaneous social context (Cosmides and Tooby 1987).

Daly and Wilson (1988) then postulated four evolutionary based reasons for parental child killing that resonate with other motivational taxonomies, including: a low quality of child, limited parental resources, paternal uncertainty, and coercion by others.

The fact that homicide is most likely in the first day of life is consistent with this evolutionary view because the child's reproductive value to the parent increases with the child's age, relative to the degree of ongoing parental investment required (Friedman et al. 2012a). The parent is most commonly a single mother of limited means who kills the neonate when the father is not present or does not know about the pregnancy (therefore lacking in any paternal investment).

Scarce financial, emotional, and sociocultural resource availability to care for an unwanted child are similarly consistent (Friedman et al. 2012a).

Examples of coercive motivations vary but it is notable that sex-selective neonaticides in the developing world could be considered as adaptive in response to social coercion (Friedman et al. 2012a).

It is also not surprising then that step-parents (including both step-fathers and step-mothers) kill with different motives than biological parents. Fatal maltreatment of older children is notable for higher rates of step-fathers. This is also reflected in their methods of murder. Biological parents more often kill in rapid ways such as shooting or smothering whereas step-parents more often kill "accidentally" after chronic beating and or maltreatment (Weekes-Shackelford and Shackelford 2004).

Evolutionary psychology is thus helpful in establishing sets of patterns whereby some forms of parental child killing appear "predictable" and may be consistent with ancient cognitive processes that evolved in response to similar proximal selection pressures to those of our distant past. However other subtypes of parental child killings do not so obviously follow evolutionary principles.

Mental Illness and Infanticide

An analysis of parental child killing in humans from an evolutionary psychological lens enables us to conceptualize circumstances under which a parent killing their child may once have been an adaptive reproductive strategy, albeit in a prehistoric setting. Altruistic homicide, however, is something of a misnomer in evolutionary terms since there is no way a deceased child can directly pass on their genetic inheritance to offspring.

A nuanced consideration of this evolutionary conundrum could envisage loving parents making a reality-based assessment about relieving a child of severe pain or suffering. However, this decision would require a parent to be able to make an accurate and informed assessment of the child's suffering. Killing an older child, from a parental perspective, is a less sound evolutionary strategy. The degree of parental investment is significantly higher and, as a child ages so do the parents who

are generally older and with arguably less time to raise another child to adulthood.

It is interesting, then, that research supports increasing rates of mental health problems among parents of either gender in relation to killing older children. It is more probable that many of these parents develop nihilistic cognitive distortions in assessing the perceived circumstances of their child. They may, for example, misinterpret the extent of the environmental stressors or feel guilty as part of a depressive illness. Indeed, the further the circumstances of a filicide move away from an evolutionary informed prediction, the more likely there is to be a more florid failure of reality testing in the parent.

One could consider a hypothetical composite case of a 38-year-old professional woman, married with no other children. She has a university education and is wealthy and has a supportive extended family network and yet is found to have killed her 3-week old son in a bath.

There would be a little apparent adaptive advantage in this scenario although the mother in the vignette is a common presentation to mental health services with the onset of depression in the perinatal period. Clinical understanding indicates both depression and psychosis in the postpartum period can also result in psychotically motivated homicides. Predictably unpredictable, the nature of the delusional motivation of a woman with postpartum psychosis to kill their child may be so bizarre as to defy any rational analysis, let alone an evolutionary one.

Consideration of parental developmental disorders are also important as these too may lead to distortions in cognitive impressions and that may be relevant to child killing. Narcissistic-personality disorder has, for example, been noted as part of the parental psychology in cases of revenge killing. Low intelligence or intellectual disability may also potentially limit the capacity of the parent to consider and accurately evaluate the true extent of support or resource availability.

The suicide of a parent is particularly notable when older or multiple children are killed. Suicide has had a social function in some societies, such as Japan and Samoa, to defer stigma and shame from individual acts that may disgrace the wider family

and thus reduce their combined genetic viability. Some evolutionary theorists would argue this is then an adaptive behavior as way of protecting resources for an extended genetic heritage.

However, psychological autopsies on such parents are rare and are at best retrospective. Committing suicide after killing one or multiple biological children is such a devastating violation of evolutionary prediction, that these perpetrators are likely to have had elevated rates of serious mental illness.

Evolutionary Psychology on the Law, Science, and Medicine

Understanding that humans have evolved to have cognitive mechanisms that process and evaluate relevant environmental information has enriched our understanding of parental child killing. Identifying which individuals facing certain stressors in our contemporary environment that most resemble those of the past is essential in identifying those who are most at risk of killing and of being killed.

For neonaticides, and most filicides, the scarce resources are a common factor strongly implying a need for better social programs and support for parents. Similarly, the evolutionary risk of “poor quality offspring” is noted in physically and psychologically disabled children being at greater risk. More could be specifically put in place for parents of these children and clinicians should be aware of this potential risk.

Education for at-risk age groups could target sexually active teenagers in relation to primary prevention measures for unwanted pregnancies. Relationship awareness and parenting courses could potentially highlight the increased risk of step-parental violence and target more specific therapeutic or social assistance.

A key finding often overlooked in evolutionary theory is when things go awry. Rather than attempting to reconcile errant examples of child-killing with evolutionary theory, accepting the role mental illness can play in distorting prehistoric cognitive mechanisms within a modern setting is also informative. Early screening for

mental illness and substance abuse, and their appropriate treatment is paramount.

More recently, our understanding of the human genome and discoveries in field of molecular genetics have advanced our understanding still further. Informed by evolutionary theory, the field of epigenetics seeks to identify how early environmental conditions may variably affect complex molecular cascades leading to the expression of specific DNA sequences. The biochemical expression of these may predispose an individual to certain complex behaviors under certain conditions.

The implications of such research will continue to further help identify target groups and further interventions in the future. It no doubt also is of interest to clinicians in assisting society in the assessment of those parents charged with killing a child. An understanding of evolutionary principles can thus help a clinician judge what is often a fine line between cognitive reality, cognitive distortion, and delusion.

However, clinicians are only ever able to advise a court in relation to the possible motives whether they be aggravating or mitigating. When revisiting infanticide law at the end of this chapter, it is interesting to note that it mitigates and (at least partially) partially exculpates younger women who behave in way that evolutionary theory would predict, effectively younger mothers who kill their younger children.

Infanticide legislation does not include parents of either gender who actually kill due to mental illness, who tend to rely of defenses of legal insanity. Using evolutionary psychology as an explanatory model, it has been “argued that infanticide legislation is at best unnecessary and at worst misapplied, in that it exculpates criminal intent and fails to serve those for whom an infanticide defense might otherwise have been intended” (Friedman et al. 2012a, p. 585).

Conclusions

Where a society positions itself on this legal continuum is for that society to determine in light of

its own views on childbirth. However, it is certainly notable that most societies have a clear understanding of where a child homicide by a parent is considered a crime or not. Moreover, many societies have laws allowing the state to assist in the termination of an unborn child. The relative availability of legal termination to mothers, young or old, at risk of an unwanted pregnancy varies greatly and is an ethically and emotionally fraught topic.

Nevertheless, the act of parental child killing has been a stable expression of human behavior for millennia and its universality is expressed in a range of cultural archetypes over millennia. Perhaps more surprising however has been the persistence of a social acceptance of the behavior at least to some degree. The fact that at least our partial collective tolerance for infanticide under certain circumstances exists implicates us as holding complicit the same universal cognitive programming of shared evolutionary heritage.

Definition

A set of aggressive behaviors destined toward the elimination of younglings, usually a dependent infant or hatchling. The attacker often obtains a fitness benefit by targeting the offspring of conspecifics. Due to the costs associated with losing a youngling, parents often employ an array of physiological and behavioral tactics to decrease the risk of infanticide.

Introduction

Although nowadays research on nonhuman infanticide has lost most of its controversial nature,

three decades ago studies on this subject generated heated debate concerning the adaptive function of eliminating infants (Sommer 2000). Due to the costs associated with producing and rearing offspring, killing younglings was interpreted as a pathological behavior with no apparent adaptive benefits. This view considered that selection would favor the inhibition of lethal aggression against conspecifics, which, when observed, was the product of abnormal conditions. Adaptive hypotheses developed during the late 1970s and early 1980s contraposed the notion that infanticide was a pathology (Hrady 1979; Sommer 2000). The following sections provide an overview of these perspectives.

Adaptive Hypotheses on Infanticide

Sarah Hrady (1979) provided a detailed classification of infanticide based on its underlying adaptive function. Therefore, eliminating infants could be due to (1) exploitation, (2) resource competition, and (3) parental manipulation (4) or as an alternative sexual strategy. Infanticide is exploitative if the death of the infant provides a direct benefit to the attacker, such as in instances of cannibalism (Hrady 1979). Exploitative infanticide may also occur as a by-product of agonistic interactions in which an adult may sequester a youngling with the goal of decreasing the risk of experiencing aggression from a third party. However, in the process, the infant may die due to starvation or injury (Hrady 1979). Similarly, curious individuals mishandling the offspring, such as dominant members of the group, could also lead to unintentional infanticide.

Due to the finite nature of resources, some organisms may decrease the costs associated with agonistic interactions by killing vulnerable individuals. Conditions of intense resource competition may positively select for the occurrence of infanticide, with the attacker, and his kin, gaining access to resources and removing future rivals (Hrady 1979). Although aggressors could target both male and female infants, depending on the type of resource contested, the sex of the infant may increase the risk of being the target of

lethal aggression. For example, if females are scarce in the group, males should eliminate male infants, whereas if food is limited, females are predicted to kill female infants (Hrady 1979).

The third type of infanticide, parental manipulation, is observed when the costs of producing and rearing an offspring jeopardize the survival of the parent or its siblings (Hrady 1979). According to Hrady (1979), infanticide as a form of parental manipulation is associated with an array of socio-ecological conditions including resource scarcity, inhabiting high-risk environments, the presence of older siblings, or the inherent fragility of the infant due to morphological or physiological abnormalities. For Hrady (1979), this type of infanticide may also be the outcome of parental neglect. In some avian species, females are known to have more hatchlings than the number for which they are certain that can provide. Brood reduction functions as insurance against complete clutch failure such as during unpredictably dire ecological conditions (e.g., famines, droughts, or high predation risk; Mock and Forbes 1994; Mock 2004). It is not uncommon, however, for all hatchlings in a brood to survive under better environmental settings. The occasional resource scarcity imposes considerable costs on the parents that risk losing all offspring due to energetic and temporal constraints. In response, the adults allocate most of their resources to few younglings, such as first- and secondborn hatchlings, increasing the risk of the rest of the offspring dying due to weather exposure, disease, or starvation. In some species adults do not interfere when younglings attack their siblings (Mock 2004), blurring the line between siblicide and infanticide.

Hrady provided a fourth hypothesized adaptive function for the elimination of younglings. Observations conducted with eutherian mammals indicated that most of the individuals who killed younglings were males, and frequently the animals killed were infants. This pattern was hypothesized to occur due to the fact lactational amenorrhea reduces males' mating opportunities. By eliminating infants, males were able to restart the estrus cycle of females. Moreover, rather than avoiding the infanticidal male, the targeted female often copulated with the aggressor. Therefore, this

view often referred to as the sexual selection hypothesis, considered infanticide as an alternative sexual strategy.

Risk of Infanticide by Males in Nonhuman Mammals

Among the various socioecological factors, life history traits have been found to predict infanticide. The ratio between the lactation and gestation in eutherian mammals influences the presence of postpartum matings. Species with a gestation period longer than lactation will be more likely to exhibit postpartum estrus, facilitating postpartum copulations restricting the evolution of infanticide (van Schaik 2000). Although a longer gestation decreases the likelihood of infanticide, species with large litters may still be at risk of due to the negative association between the number of offspring and future reproduction (van Schaik 2000). Alternatively, species with a shorter gestation period relative to an extended lactation will be less likely to have postpartum estrus and have a higher risk of infanticide. However, clades with a prolonged lactation and short gestation can decrease the likelihood of infanticide if the species breeds seasonally (van Schaik 2000). A cross-species comparison revealed that infanticide by males in nonhuman primates exhibited a high lactation/gestation ratio (van Schaik 2000).

Counterstrategies Against Infanticide by Males in Nonhuman Primates

Since females are expected to invest more heavily in offspring production than males (i.e., parental investment hypothesis; Trivers 1972), according to the sexual selection hypothesis of infanticide, females should develop a series of counter strategies to decrease the risk of having their infants killed by male conspecifics. Females can therefore either confuse the males' paternity certainty or concentrate it on a single male (Palombit 2012). Concerning the former, confusing paternity is achieved through an array of behaviors and physiological changes such as mating with multiple

males, extending the estrous period, copulating before ovulation and after conception, and either concealing ovulation or increasing the advertisement of sexual receptivity (e.g., sexual swellings, vocal displays; Palombit 2012). Instead, physiological and behavioral correlates of paternity concentration include limiting the matings to the male most likely to protect infanticide, advertising sexual receptivity and ovulation to increase the likelihood of mate guarding, and copulating with the potentially infanticidal male (Palombit 2012).

Females could also modify their reproductive schedules to counter the risk of infanticide. For instance, they may block their pregnancy, accelerate the weaning period, synchronize the period of ovulation with that of other females, conceive while pregnant (i.e., superfetation; Palombit 2012), or abandon the infant (Palombit 2012). However, due to the fact physiological strategies are less flexible and plastic than behaviors, it is expected females should also display individual and social defenses against infant killings. Attacking infanticidal males, increasing the level of protectiveness and vigilance, as well as avoiding or distancing from the group, are among some of the individual reactions reported by the literature (Palombit 2012). In addition to responding by themselves, females had been known to employ social strategies such as establishing long-term aggregations, developing coalitions and alliances with other females, preferring small groups (therefore decreasing the risk of male immigration), and rejecting immigrant females to maintain the current group size (Palombit 2012). In addition to developing alliances with other females, mothers with infants can also establish relationships with protecting males (Palombit 1999). However, depending on the socioecology of each species, these associations can range from short-term coalitions to long-term bonds (Palombit 2012). Comparative phylogenetic examinations suggest infanticide and social monogamy coevolved across 230 nonhuman primate species (Opie et al. 2013), a result that not only draws a clear connection between the coevolution of social monogamy and infanticide, but it also calls into question the notion that biparental care preceded pair bonding.

Infanticide by Females

Infanticide by females, though considerably less common than infanticide by males (especially in eutherian mammals), has also been observed. According to Digby (2000), infanticide poses a considerable risk for younglings living in multi-female groups. For the author (2000), additional species-specific risk factors include the presence of altricial offspring, leaving the infant alone or unprotected, the physical proximity of infanticidal females, the presence of alloparental care, and the degree of power variation across individuals in the group. The benefits obtained by female as opposed to male perpetrators of infanticide fit better with the predictions made by the resource competition and the exploitation hypotheses. Parental manipulation is also hypothesized to be associated with infanticide by females, with young and subordinate mothers facing a life history trade-off of investing either in current or in future offspring. In cooperative breeders, killing the infants of subordinate females increases the likelihood of allocating resources and attention to the offspring of dominant individuals. Social systems in which there is active suppression of the reproduction of subordinate females, the costs of female dispersal are higher than remaining in the local group, and the dominant female holds a reproductive monopoly, increases the risk of infanticide by females (Digby 2000). Although sexual selected female infanticide also occurs, in most instances, this behavior is correlated with sexual reversals, wherein males invest more in parental care than females (some females of sexually reversed species also exhibit ornaments and armaments). By eliminating the offspring of other females, the perpetrator can obtain additional resources and care.

Conclusion

Even though initially infanticide in nonhuman species was interpreted as the product of pathological behavior, the current evidence supports an array of adaptive hypotheses wherein eliminating infants decreases resource competition, serves

nutritional purposes, buffers against the aggression of other individuals, and increases the fitness of relatives. Concerning nonhuman primates, the current evidence provides strong support for the sexual selection hypothesis. Some of the risk factors associated with infanticide in non-human primates are 1) a slow life history; 2) a lactation period longer than the gestation period, and 3) living in societies with high male reproductive skew. In response to this persistent threat, females evolved a repertoire of physiological and behavioral tactics, ranging from altering their reproductive schedules to developing coalitions and alliances with other females or resident males. Although, in eutherian mammals, males are often the perpetrators of infanticide, females may also eliminate infants to decrease future competition with other offspring.

Definition

The factors that increase the prevalence of infidelity within the context of exclusive relationships.

Introduction

Infidelity may include a broad range of behaviors depending on the perspective of the individual. Different behaviors from flirtatious acts, to emotional involvement, to sexual intercourse may or may not be considered infidelity. Although it may be hard to pinpoint infidelity with absolute precision, its negative consequences are easy to detect. Infidelity is related with negative health outcomes and is the most common reason for marital dissolution around the world. There are different factors that increase the risk of infidelity, and these factors that make people more prone to infidelity can be examined in three levels: personal level, relationship level, and contextual level.

Personal Level

Some individual differences are reported with a higher risk to engage in infidelity. One of the most consistent examples is gender. Although recent studies note that the gap is closing, men are still more likely to engage in infidelity than women (Treas and Giesen 2000). The personality of the individual is another factor. People with higher levels of neuroticism and narcissism are more likely to engage in infidelity (Fincham and May 2017; Whisman et al. 2007). In addition, people with insecure attachment are more likely to search out for alternative mates (DeWall et al. 2011; Russell et al. 2013).

Other than individual differences, the attitudes and experiences of the individual may also play a role in the risk of engaging in infidelity. It has been shown that permissive attitudes toward sexual interests and a general willingness to have casual sex are related to higher levels of infidelity (Treas and Giesen 2000). Moreover, people who have previously engaged in infidelity, who were exposed to parental infidelity, and who had had greater number of sexual partners before marriage are more likely to engage in infidelity (Fincham and May 2017).

Relationship Level

Infidelity can happen in any relationship, and relationship-related factors can play a role in infidelity. Yet, research investigating the risk factors of infidelity focuses primarily on the personal level. Therefore, relatively less is known about how relationship dynamics influence the likelihood of infidelity. Nonetheless, some studies have examined infidelity in the relationship level. Two of the main findings from the level of relationships are that sexual dissatisfaction and decrease in commitment toward the partner predict infidelity (Allen et al. 2005). Moreover, when a partner perceives threats internal to their relationship, such as partner's expression of criticism, they possess less sexual desire for their partner which in turn predicts greater attraction to

alternative mates (Birnbaum et al. 2019). In other words, thinking about moments when they felt intensely disappointed, hurt, or let down by their partner leads the ruminating partner to engage in more approach-related behavior like overt flirtation toward attractive, alternative mates.

Contextual Level

The people in the relationship and the relationship itself impact the risk of infidelity. But contextual factors also have the power to influence an act of infidelity. For example, traveling to another city is one of the contextual factors that increase the risk of infidelity. The number of days spent for work travel away is highly associated with infidelity since there is less risk of getting caught by one's primary romantic partner (Træen and Stigum 1998). Even if a partner is not travelling and staying in your location, you might be in a higher risk for infidelity depending on your location. It is shown that people living in warmer and urban areas are more likely to engage in infidelity. Lastly, people around the individual may also influence the risk in engaging in infidelity. Infidelity is more likely when individuals' peers also engage in infidelity or support their infidelity-related behaviors (Fincham and May 2017).

Conclusion

Personal, relational, and contextual factors discussed in this entry provide several lenses through which to understand the risk factors of infidelity. It should be noted that this entry focused on the factors that are related with higher infidelity risk. Yet, there are also factors that have been identified with lower risk of infidelity, for example, dyads who have similar characteristics (e.g., same religion, education level) and dyads in which both partners are employed are less prone to infidelity (Brooks and Monaco 2013). For more information on prevention of infidelity, see the entry by Sacco and Brown (2018).

[Infinite capacity](#); [Unlimited storage](#)

Definition

Infinite storage refers to the unlimited capacity that is assumed to exist for long-term memory.

Introduction

Long-term memory (LTM) has always been viewed as a rather distinct type of memory compared to short-term memory (STM) or working memory (WM), not only for its long-lasting maintenance of information but also because of its enormous capacity. It was always assumed that storage capacity in LTM is unlimited and thus one can remember an infinite number of things. Difficulties with memory capacity in LTM have usually been attributed to problems in encoding and not so much due to limitations in storage. In this section, the idea of infinite storage of LTM will be briefly discussed, in light of the latest research findings.

Infinite Storage: Is It Really?

One of the seminal papers in the history of memory research was published by George Miller in 1956, who estimated that STM has a limited capacity of seven plus or minus two digits or items, which meant that the range of STM capacity was between five and nine items. More recent studies argue for an even smaller capacity, at least for visual information, of around four items (Brady et al. 2011). Interestingly, the capacity of

STM or WM rather is strongly associated with performance in cognitive tasks and intellectual capacity in both animals and humans, and luckily, it seems to improve with practice (Constantinidis and Klingberg 2016). Despite the possibility of increasing the capacity of WM, it is still greatly limited and in no way its capacity can be compared to that of LTM.

LTM is believed to have infinite capacity for memory storage although nobody has been able to measure it. It is likely that the capacity is very large. Brady et al. (2008) evaluated the capacity of visual LTM and found that even subtle differences in visual stimuli were remembered by the participants who showed good recognition for 2,500 objects. It is logical that larger memory capacity may be more advantageous compared to smaller memory capacity. Perhaps practice in a particular domain may be important (Constantinidis and Klingberg 2016) but genetics probably also plays a significant role (Montag et al. 2014).

Storage of information in LTM can be viewed in terms of concepts or nodes that are interconnected in the brain, as it is proposed by the spreading activation networks, emphasizing the connections established during learning (Collins and Loftus 1975). It turns out that there is tremendous capacity to retain information learned and that is indeed reflected in the brain by increased branching and synapses in the neurons involved, known as the physical traces of memory or engrams (Tonegawa et al. 2015). People who are highly skilled in certain domains seem to have larger brain areas that support those skills, suggesting increased dendritic branching and synapses associated with that knowledge, compared to people that may lack that level of training as documented in musicians, for example (Schneider et al. 2002). So, if memories have a physical trace, can it be that a maximum capacity can be reached, when one may no longer remember more? Can there be such thing as infinite storage if the nature of the stored information is physically coded?

The hippocampus may help to answer the above questions and enhance our understanding

as to what may be happening in other areas of the brain, when it comes to increasing knowledge in a limited space. Recent studies suggest possible mechanisms through which the infinite storage of LTM may be possible. It is well accepted that following learning, the new information is stored for longer-term use through the process of consolidation which renders newly learned material permanent, at least until the next retrieval (Tonegawa et al. 2015).

Most studies have looked at hippocampus-related memories and showed that consolidation initially takes place in the hippocampus and then the information is dispersed to other areas of the neocortex, which were involved during the encoding phase (Davis and Zhong 2017). In addition, a specific pattern of neuronal firing emitted from the hippocampus during slow-wave sleep (SWS) known as sharp-wave ripples (SWR) seem to weaken the synapses between hippocampal neurons which encode old memories but not those which encode newly learned information (Norimoto et al. 2018). Thus, instead of considering LTM as an infinite storage capacity construct, LTM should be instead redefined as a construct involving not only the hippocampus but also numerous areas of the neocortex which themselves become the hosts of memory traces. In addition, the capacity never reaches maximum capacity due to the fact that there are processes in place that actively pursue the elimination of memory traces which are thought to be unnecessary or redundant (Davis and Zhong 2017).

Thus, although the findings regarding the aspects of LTM which have to do with its infinite ability to store information are very exciting, there is still a great deal of work to be done in order to fully understand the nature of this infinite capacity in regards to the different types of memories, different animal species, and the molecular players involved in both enhancing memories and erasing memories. So far, it seems that LTM can maintain this condition of “infinite storage” because it may be very selective. Moreover, given that memories are dispersed throughout different areas of the brain, its capacity can indeed be quite enormous.

Conclusion

It turns out that the idea of infinite storage of LTM is indeed true but not because our brains can expand endlessly. It is because the brain is equipped with mechanisms which allow itself to delete information and create space for new learning. So, in principle, there is no limit in what may be learned and memorized. LTMs which are judged to be important will be saved at the expense of other bits of knowledge that may be lingering without much use and thus will be erased. The infinite storage is made possible, not because of a truly unlimited space but an efficient system which makes the most of a limited space, the hippocampus and the brain as a whole, and an amazing ability to adapt to a changing environment. Decisions on what information is important and thus should be saved and which information is useless and thus should be deleted are made constantly, especially during sleep, throughout life.

Information About Likely Combat Success

Definition

The same psychological strategies that often lead to unnecessary war may often prevent war as well

when overconfidence and bluffing encourage others to back down rather than fight.

Introduction

If both sides in combat made accurate assessments of their likelihood of success, war should not have to occur at all from a classical economic notion of rationality. If one side believes it is going to lose, it should not fight unless attacked but rather should make accommodations to the dominant side that preserve more life and treasure than would likely be lost in war. However, given the endemic nature of war, such accurate calibration clearly does not take place much of the time. But if that is the case, then the puzzle for evolutionary models is why so many people make so many mistakes so much of the time in making decisions about their likelihood of victory in combat. In other words, as Wrangham (1999) asked, “Is military incompetence adaptive?” This is plausible once observers realize that the same strategies that often lead to unnecessary war may often prevent war; those cases of the dog not barking in the night are not observable and thus hard to measure objectively. But if fitness gains accrue differentially to those who manage to win without fighting by employing these strategies more often than having to fight and losing, it is possible to see how such strategies might be preserved. And indeed some evidence in support of this hypothesis exists.

Standard Explanations from a Rationalist Perspective

There are several standard explanations for war from a rationalist perspective that have been and can be dismissed. And evidence exists for the operation of some adaptive mechanisms that inadvertently lead to systematic and even predictable errors in judgment under some specific environmental and ecological conditions. In addition, since we would expect combat to have been largely differentiated by sex across millennial time, the appearance of these biases should occur more in men than in women, and indeed this appears to be the case, in a process facilitated if not instigated by, specific hormonal pathways.

Several models in political science argue that war can occur within the context of an economically defined notion of rationality. In perhaps the most influential of these arguments, Fearon (1995) argues that state leaders can make rational miscalculations, often due to lack of information. He suggests that this can result from a number of causes including commitment problems; difficulties dividing up seemingly indivisible issues, such as sacred territory; and access to private information, such as when one side has information the other sides does not, such as number or quality of weapons, and the incentive to withhold or misrepresent this information. Other arguments from within a rationalist framework make similar arguments based on the notion that leaders wish to stay in power and often they can facilitate that goal, even at great cost to their population, by initiating war (Bueno De Mesquita et al. 2005). Although these models remain influential in political science and the study of international relations, they can be criticized for numerous failings, not least, the conflation of individual decision making with state level outcomes, as well as their failure to align with empirical demonstrations of individual decision-making strategies and biases.

Potential Sources of Adaptive Military Incompetence

Richard Wrangham’s (1999) framing of the question regarding the value and utility of seeming military incompetence allows for a deeper investigation into the reasons why such behavior might have emerged and persisted. In his original work, he discounted contrary explanations that focused on individual stupidity, psychological maladjustment, or cognitive limitations to explain decisions that result in inaccurate assessments of the likelihood of success in combat. Importantly, he provided a critical distinction between raids, where assessments tend to be accurate, and therefore costs are low, and battles where assessments are often inaccurate, and therefore costs are often high. He proposed two possible explanations for this latter miscalculation: (1) performance enhancement, wherein negative perspectives are suppressed, as, for example, might occur when one side underestimates the

quality of the other sides' warriors and (2) opponent deception through bluffing. Subsequent work by Johnson et al. (2002) provided empirical support for the latter hypothesis using data from the US Historical Evaluation Research Organization.

Opponent deception hypothesis rests on the notion that positive illusions can serve an adaptive function. Opponent deception may be most successful when leaders are able to deceive themselves as well; this kind of self-bluffing proves particularly effective because it reduces the risk of behavioral leakage, whereby observers can see that the leader is faking. Such overconfidence also saves the energy that self-deception might require, thus freeing additional resources for labor recruitment or combat itself. Highly confident leaders may be able to recruit more labor from fence sitters because they convey a feeling of inevitable victory, and everyone likes to be on a winning side where they can derive benefits from the gains of victory. More importantly, opponent deception may scare off the opponent without having to fight at all, or may deter potential aggressors from instigating a fight they fear they may not win.

Thus, opponent deception may prove adaptive in several different ways. Before the emergence of the militarized threshold, victory in combat was secured largely through size and surprise, although some element of superior strategy may have helped as well. But if leaders could increase the size of their following through overconfidence, they would be more likely to prevail in actual combat. In addition, if they could prevent opponents from attacking or get inferior powers to acquiesce without fighting through successful bluffing, then fitness gains would accrue to those who possessed such tendencies, even if some percentage of the time, resulting combat led to many deaths.

The role of overconfidence in triggering war and the consequences of positive illusions in instigating conflict have been explored in depth in Johnson (2009). In their work on the evolution of overconfidence, Johnson and Fowler (2011) present a model showing that overconfidence maximizes individual fitness, thus leading to its prevalence in populations despite the obvious costs. They showed that as long as the benefits of scarce or disputed resources outpaced the cost

of competition, overconfidence would remain a stable strategy. This can happen, for example, because overconfident people may be able to get others to back down without a fight, securing resources without cost. In addition, overconfidence can often encourage followers to join, thereby increasing numbers and making victory more likely. By contrast, they also demonstrated that more economically rational models remained robust under much more limited conditions.

Sex Differences

An additional important consideration has to do with the sex-specific nature of these occurrences. Women would be more likely to place a higher premium on their physical safety because in the environment of evolutionary adaptation, children required more investment from mothers than fathers in order to survive (Campbell 1999). According to Campbell, the evolved mechanism designed to secure the greater safety of women, in part by reducing their own aggressive behavior, involved a lowered threshold for fear in the face of activities that risked physical injury. By contrast, men, particularly low status ones, may have been able to secure greater reproductive access by achieving success in battle, either through obtaining resources such as livestock, bride capture, or simply as a result of higher status.

Work which has examined the characteristics of these sex differences in positive illusions in the context of simulated war games investigated some of the conditions that might prompt or prohibit aggression (Johnson et al. 2006). In these studies, individuals were overconfident in general in their expectations of success, although men vastly more so than women. Interestingly, those who were more overconfident were more likely to attack their opponents, even if they had not been attacked first. Finally, testosterone levels did seem to be predictive of expectations of success, suggesting at least one potential hormonal pathway by which overconfidence and beliefs about success might be endogenously generated. However, these differences only explained the divergences between men and women and not the differences that emerged within each sex, suggesting that hormones

alone do not mediate the entire process, although they may contribute to differences between the sexes. As these authors conclude:

[O]ur key finding is that males were overconfident; and males who *were* more overconfident were *more likely* to launch wars. This remains a concern irrespective of its origin: overconfidence among decision-makers may increase the chance and/or costs of war because it leads to inflated estimates of success – not necessarily of winning outright, but of likely performance, the costs involved, vulnerability to risk, and the ability to control events if things go badly. (2518, italics in original)

In addition, narcissism predicted both overconfidence and unprovoked attacks in males. In this study, one of the interesting findings related to changes in assessments that men and women made after they received feedback about their performance in the wargame. At the outset, everyone was asked how likely they thought it would be that they would win relative to everyone else who played. Men proved vastly more confident in these assessments than women. After they played their game, each person had some direct and immediate feedback about their performance relative to at least one other person: their opponent. When asked after they received this feedback, sex differences in perceived performance also changed differentially. Men who had won their game vastly increased their assessments, whereas men who lost only slightly downgraded their evaluations. By contrast, women who won only slightly increased their perceived rankings, if at all, while women who lost drastically decreased their sense of their overall performance. This matters because past experiences help condition future expectations and behaviors. Men who become more confident after small victories then prove more likely to attack in the future, raising prospects for overall conflict.

Conclusion

Assessments about likelihood of victory are important because most individuals would be loath to launch an attack they believe they will lose, although most would certainly be prepared to defend against an unwanted attack, highlighting the importance of offensive versus defensive contexts in undertaking combat. But the information

that goes into calculating these expectations of victory is not as straightforward as it may seem. Like many other biases in human judgment and decision-making, the biases that lead to overconfidence, particularly in men, may, counterintuitively, be adaptive. Overconfidence can spur the ambivalent to action, bluff and bully the weak or scared into submission, and provide valuable benefits at lower cost on average. Various hormonal and experiential pathways may help precipitate these actions, beliefs, and behaviors. However, these inclinations in information calibration seem to apply more strongly to men than to women, precisely because the damage wrought by physical injury to women exerted higher fitness costs than on men.

Making accurate assessments of the likelihood of success in combat constitutes only one of several factors that may go into decisions about going to war, along with the other variables such as the nature of the risk and threat, the potential benefits to both leaders and followers, and the expected costs. The expectations of success influence most heavily these assessments of relative costs, but from an evolutionary perspective, such costs cannot be determined exclusively according to immediate costs, either financial or physical, but must also be analyzed in terms of the long-term consequences of overconfidence on fitness outcomes.

Definitions

Information – A statistical measure of uncertainty involved in the selection of a communicative message in a particular situation (Weaver 1949); a measure of unpredictability of which of a set of possible messages is selected or transmitted by an information source.

Information-Processing – a set of instructionist models of brain and cognitive activities that assume meaningful (communicative) environmental stimuli instruct internal, brain-based, algorithmic programs on how to build or organize an adaptive response to environmental stimuli.

Introduction

Biological and cognitive psychologists rely heavily on the concepts of information, information-processing, and symbolic representations to describe neurocognitive activities; they seldom consider brain activity in other ways (Epstein 2016). Unfortunately, when an idea or paradigm becomes orthodoxy, it stops us from asking questions that could lead to more productive theoretical conceptions of neurocognitive activities (Brette 2019; Epstein 2016). The present entry describes the use of information-processing terminology in Psychology, acknowledging its descriptive utility, but describes problems with regarding information and information-processing as causal explanations of bio-psycho-social events. It also outlines a proposal that brain systems and behavior work by selectionist rather than information-/instruction-based processes (Edelman 1987).

Information Is Distinct from Meaning and Often Reified in Psychology

Psychologists sometimes reify “information” and treat it as a concrete, meaningful mechanistic explanation, anchored in physical (environmental, biological, and biochemical) causality. But, confusing *information* with the *meaning* of individual communicative messages, or with the knowledge contained in messages, is misleading (e.g.,

Weaver 1949). Information, in the Shannon-Weaver sense, is a *statistical description* of uncertainty regarding the “choices,” from a set of possible options, a receiver makes from a meaningful message:

The concept of information developed in this theory at first seems disappointing and bizarre-disappointing because it has nothing to do with meaning, and bizarre because it deals not with a single message but rather with the statistical character of a whole ensemble of messages, bizarre also because in these statistical terms the words information and uncertainty find themselves partners. (Weaver 1949, p. 14)

Because information in the Shannon-Weaver sense is a *statistical-mathematical* description, not a *mechanistic* explanation of events, “information-based models” are only a descriptive step toward models of biological *mechanisms*. Reified “informational” descriptions focus attention on attempts to understand a statistical invention that summarizes and describes, but does not explain, physical mechanisms. Because this sense of information is neither meaning nor a message containing one meaning, reified physical “copies” (e.g., neurally coded symbols/representations computationally manipulated) of environmental information held and processed in the brain mislead biological explanations of neural activities. Similarly, with respect to biology, Wilkins (2009, p. 1) argued:

...“information” is a homonym for a range of distinct notions, and that these notions are either of concrete properties, in which case they are little more than a periphrasis for correlation and causation, or of abstract properties, in which case they are observer-dependent. In short, if information is in the concrete world, it is causality. If it is abstract, it is in the head.

Though Useful, Information-Processing Models Aren’t Necessarily Correct Descriptions

Information theory is often instantiated within an information-processing approach to produce descriptive models of natural phenomena (e.g., human thinking). Tooby and Cosmides (1992) and Pinker (1997; 2009) wedded Evolutionary

Psychology to an information-processing approach that relies on at least three ideas: (1) despite obvious physical (and other) differences, “...brains and computers embody intelligence for some of the same reasons,” (2) our brains are *processors* of symbols that “carry information,” and (3) a set of complicated computer-like programs (complex sets of instructions/algorithms), sculpted by natural selection, produce human thinking and behavior (Pinker 1997).

Information-processing “programs” are sometimes taken literally, not metaphorically. For example, Cosmides (see Monticello and Gillespie 2015) stated:

...behavior is generated by programs in your head, and I don’t mean it metaphorically—devices that are designed by natural selection to process information and guide your behavior. Evolutionary Psychology focuses on that intermediate step of what’s the structure of those programs. And without understanding that, all you can have is sort of fuzzy relationships between insights about selection pressures and behavior as opposed to a real science of the mind.

Following assumptions of information-processing theorists, Tooby and Cosmides (1992) write:

Much of great interest can be learned by investigating the brain in neurobiological terms, but its adaptive dimension will remain invisible unless and until its mechanisms are described in a language that is capable of expressing its informational functions.

By their perspective, studying the physical properties of the brain isn’t likely to help us understand the “...functional structure of the brain” as well as an information-processing-based description can (Tooby and Cosmides 1992, p. 66). In short, although the brain is organized around physically instantiated, algorithmic programs, direct study of brain activities isn’t particularly helpful in developing descriptions of adaptive algorithms.

But, neuroscientists do attempt to study the physical implementation of information-processing concepts like neural-coded representations or memory engrams. If the brain is organized around physical information-processing devices, we should discover how information-processing programs are physically instantiated and how

brains represent “information” (the *meaning* of symbols) at each step of cognition. Some are troubled by the approach. Brette (2019) writes “[the] neural coding metaphor is a way to think about the brain that is disconnected from its causal structure” because brains are dynamically coupled with the environment, neurons are dynamically coupled to one another through timed spikes, and the neural coding idea implies “...that one part of the brain can be understood independently of the way it interacts with the rest of the brain” and the way it interacts with the environment. Furthermore, he argues “...the causal structure of the neural coding metaphor is incongruent with the causal structure of the brain” and “...cannot form a valid basis of a theory of brain function” because “...coding variables are extended measurements of activity linked to the temporality of experiments”, not “...causal variables of the underlying dynamic system.” This suggests that reified information-processing concepts (e.g., neural codes) misdirect proper brain theory: Neural “codes” may not be physically instantiated at all.

Abstract Meaning of Environmental “Information” Is in the Head

Pinker (1997; 2009) defines information as “...a correlation between two things that is produced by a lawful process.” When we consider “information” as a statistical description or a lawful correlation, however, it behooves us to avoid reifying “external” information as independent of a receiver with the mental capacity to generate (perceived) meaning.

In contrast to objective “information,” meaning/knowledge is the *perceived* structure of the surrounds and associated adaptive problems. The existence of meaning/knowledge depends on the biological and experiential nature of the receiver/interpreter. Although information may carry meaning, meaning (1) is independent of the carrier, and (2) cannot be derived from the carrier alone. Hence, meaning/knowledge is a *theoretical* term referring to pre-action use and something an organism makes/creates only

partially from the structured physical information carrier. To achieve meaning, from an information-processing perspective, an organism’s brain machinery must decode novel information in ways that create meaning for adaptive action (Ittleson 2017). Claiming that thoughts are internal representations, Pinker (1997; 2009) argued that talk of homunculi that “read” and “interpret” data structures is common in computer science, but “the homunculus that ‘looks at it’ is not a miniaturized copy of the entire system, requiring its intelligence” and “...each homunculus is required only to react in a few circumscribed ways to some of the symbols” (p. 79), so these “interpreters” are “mechanical” devices that do not require the intelligence of the whole system (p. 79).

Edelman’s Theory of Neuronal Group Selection Rejects Information-Processing

Edelman (1987) rejected information-processing (instructionist) approaches to brain organization/function in favor of a selectionist approach. He argued information-processing approaches, problematically, require precise algorithmic programs and an environment that is organized for objectively “meaningful” categorization, independent of the individual interpreter. In Pinker’s (1997) terms, “A computer is the most legalistic, persnickety, hard-nosed, unforgiving demander of precision and explicitness in the universe.” But, given that environments constantly change in novel and unanticipated ways, precise *pre-prepared rule-bound algorithmic programs* are not equipped to deal with novel or unexpected environmental change:

How and where are “programs” constructed capable of context-dependent pattern recognition in situations never before encountered? Processors of information must have information defined for them *a priori*, just as the Shannon measure of information (see Pierce 1961) must specify *a priori* an agreed-upon code as well as a means of estimating the probability of receiving any given signal under that code. But such information can be defined only *a posteriori* by an organism (i.e., the categories of received signals can be defined only after the signals have been received, either because of

evolutionary selection or as a result of somatic experience). It is this successful adaptive categorization that constitutes biological pattern recognition. In assuming the existence of informational categories in the environment or of computational programs in the brain that can produce a broad range of plastic adaptive behavior, information-processing models are forced to take a position similar to the argument of creation from design, which dominated pre-Darwinian thinking about species (Mayr 1982). Edelman (1987, p. 43)

When we reify information-processing programs, we imagine information and natural processors of it to be anchored in biological reality. Edelman's argument suggests such "programs" are anchored only in researchers' meaning-filled heads.

A strength of a theory of natural selection is that it provides an explanation of the functional adaptedness of organisms to their environmental conditions *without* the need to invoke an intentional "planner" *guiding* the design of organisms, without an entity *teaching organisms through instructions* about how to regulate their features to overcome adaptive problems. Selection, over evolutionary time, proceeds *without the environment "programming" (i.e., transferring instructions ("meaning")* the organism. Thus, we shouldn't expect organisms to possess machinery that deciphers and responds appropriately to informational messages about how to best adapt to novel environmental changes.

Edelman's "Neural Darwinism" permits environmental features (through epigenetic rules, which are useful descriptive inventions) to *select* from evolutionarily prepared "contents" of human (neural) nature during proximate developmental time. This contrasts sharply with an approach claiming the environment *instructs* and/or rearranges neural wiring based on built-in programs and their interpretation of environmental information.

Conclusion

Information and information-processing talk is used by thinkers in various fields attempting to explain the organization of cognition and behavior. Some find this terminology indispensable for

descriptions of neurocognitive mechanisms and for a rigorous Evolutionary Psychology (Tooby and Cosmides 1992; Pinker 1997). But, reifying information creates a dualistic system of explanation. Although useful for describing regularities in how brains respond to stimuli, an information-processing approach is a potentially misleading biological explanation. A search for "information," "programs," "symbolic representations," or "sets of instructions" in the neural tissue might be replaced by a search for physical causation in that tissue (Wilkins 2009). Selection, not instruction by or information transfer from the environment, shapes biological adaptations. Since natural selection rejects an "informed" programmer that builds adaptations over evolutionary time, it's plausible that the brain evolved to operate, in proximate time, by principles analogous to natural selection (Edelman 1987).

Ingredients of Reciprocal Altruism

Dennis L. Krebs
Simon Fraser University, North Vancouver, BC,
Canada

Synonyms

Cooperation; Reciprocity

Definition

A mutually beneficial exchange of goods or services.

Introduction

The term “reciprocal altruism” was introduced by Robert Trivers in his seminal 1971 paper to characterize exchanges of goods or services between two or more unrelated members of the same or different species that increase the fitness of each partner to the exchange. Trivers’ (1971) paper had a great deal of impact on the field of evolutionary biology because it offered an explanation for the evolution of altruism that could not be accounted

for by kin selection. However, the term reciprocal altruism is ambiguous. Although the proffering and reciprocation of goods and services by each member of a reciprocal exchange may be considered altruistic because actors suffer costs to bestow benefits on recipients, the ultimate effect of the exchange is biologically selfish when it produces a net gain in fitness for both participants. Adaptations that enable such exchanges have evolved because they have produced return benefits that increase participants’ fitness. Reciprocal altruism may best be viewed as a form of return-benefit mutualism (+/+ vs. −/+).

Reciprocal Altruism in the Animal Kingdom

In his 1971 paper, Trivers cited cleaning symbiosis and warning calls in birds as examples of reciprocal altruism, and suggested that reciprocal altruism was prevalent in the human species. Among the best-documented reports of reciprocal altruism in other species are those of Hart and Hart (1992), who found that impalas engage in alternate grooming, and Wilkinson (1990), who found that vampire bats are more likely to regurgitate blood for nonrelatives who have regurgitated blood for them than they are to help nonrelatives who have not helped them. In addition, primatologists reported observations of chimpanzees engaging in calculated forms of delayed reciprocity. The chimpanzees remembered who helped them, kept track of whether they owed or were owed by other members of their troupes, and repaid them – either in the same currency or in some other currency. For example, de Waal and Luttrell (1988) found that chimpanzees helped members of their groups who had helped them in agonistic exchanges (“one good turn deserves another”) and aggressed against group members who had sided with others against them (“an eye for an eye”). These researchers also found that the probability of chimpanzees sharing food with other members of their groups increased when these members had groomed them earlier in the day. With respect to the human species, Tooby and Devore (1987) included ingredients of reciprocal

altruism among three of the 15 unique hominid characteristics displayed by early humans.

Following the publication of Trivers' 1971 paper, there was a general expectation among biologists that reciprocal altruism would be prevalent in the animal kingdom, but this did not turn out to be the case. Although some biologists reported incidents of reciprocal altruism in non-human species, the prevalence of this form of conduct was lower than expected, and critics questioned whether many of the exchanges of goods and services that researchers classified as reciprocally altruistic met the criteria for reciprocal altruism, suggesting for example that they might be more appropriately classified as byproduct mutualism (Dugatkin 1997; Hammerstein 2003). In his early paper, Trivers (1971) suggested that reciprocal altruism should be prevalent in the human species because early humans satisfied such preconditions for its evolution as "long life span; low dispersal rate; life in small, mutually dependent, stable social groups . . . and a long period of parental care" (p. 45). Such conditions increase the probability that individuals who help others will encounter them in the future and receive goods and services from them in return.

The Structure of Reciprocal Altruism

To engage in reciprocal altruism, two or more members of the same or different species must behave in ways that increase each other's fitness. Participating individuals play two roles: donor and recipient. Individual A donates fitness-increasing goods or services to Individual B at a fitness cost to himself or herself, and Individual B donates fitness-increasing goods or services to Individual A at a fitness cost to himself or herself. Although two or more individuals may donate goods or services to one another simultaneously, most incidents of reciprocal altruism involve a delay: Individual A, in the role of donor, suffers a cost to proffer a benefit to Individual B, in the role of recipient, then Individual B (now the donor) repays Individual A (now the recipient). Although two or more individuals can gain significantly more

fitness-increasing benefits by engaging in reciprocal altruism than they can by failing to reciprocate, there are significant obstacles to the evolution of reciprocal altruism. One pertains to the origin of adaptations mediating the exchanges. How could donors acquire adaptations to make the first costly helping overture, and how could recipients acquire adaptations to suffer the immediate costs of reciprocation? The second obstacle pertains to the temptation to cheat and engage in free-riding. How could individuals acquire adaptations that induce them to resist the temptation to receive without reciprocating or to take more than their share and give less in return?

Ingredients of Reciprocal Altruism

The main ingredients of reciprocal altruism are (a) exchange partners, (b) goods and services, (c) giving and receiving, (d) costs and benefits, (e) gains in trade, (f) strategies, (g) direct and indirect returns, (h) antidotes to cheating, and (i) group contexts.

Exchange Partners

To engage in reciprocal exchanges, individuals must have one or more partners. The range of potential partners may vary across species and within species at different times and in different places. In some contexts, individuals have virtually no choice of partners, whereas in other contexts they have a wide range of choice. Investigators have found that partner choice favors cooperation in such species as yucca moths, fig-wasps, and clearer fish (Dugatkin 1997). Potential partners may vary in their capacity to maximize the benefits of recipients. It is in individuals' interest to select dependable and generous partners who possess resources of value to them and who are most likely to pay them back and to maximize their benefits. The ability to select and reject partners, as well as the value of forming long-term partnerships and friendships with members of one's group,

probably played an important role in the evolution of reciprocal altruism in the human species (Tooby and Cosmides 1996).

Goods and Services

The types of goods and services that are reciprocated in the animal kingdom pertain directly or indirectly to survival and reproductive success. The main goods that are exchanged are the types of food consumed by the species in question – for example, meat, grubs, worms, eggs, ectoparasites, and blood (e.g., in vampire bats). Among the most prevalent services exchanged are protection and defense, coalitional support, mating privileges, and grooming. Individuals may exchange the same or different goods or services. For example, chimpanzees engage in reciprocal grooming and exchange grooming for food and coalitional support (de Waal and Brosnan 2006). The range of goods and services exchanged in the human species is vastly larger than the range in any other species.

Giving and Receiving

Reciprocal altruism consists of giving and receiving, which may vary in terms of the number of exchanges individuals have with one another, the time interval between giving and receiving, and the balance of giving and receiving.

Number of exchanges. Individuals may engage in one-shot exchanges of goods and services or in a large number of successive exchanges. The number of exchanges engaged in by reciprocating partners may have a significant effect on the form of the interaction and the evolution of reciprocal altruism because, as demonstrated in game theory research using the Prisoner's Dilemma, the optimal strategy in one-shot exchanges is to behave selfishly, whereas the optimal strategy in repeated exchanges is to cooperate. The source of this difference lies in the costs experienced by selfish individuals who are treated selfishly or rejected as partners in future exchanges. However, when

individuals anticipate that they will engage in a finite number of exchanges and are able to predict the final exchange, each individual may anticipate that his or her partner will fail to reciprocate in the final exchange and decide not to reciprocate on the second to last exchange, and so on back to the first exchange, precipitating the disintegration of the reciprocal relationship through backward induction.

Timing of giving and receiving. Individuals may exchange goods and services simultaneously or after delays that range from moments to years. For example, primates may groom one another simultaneously or sequentially. Impalas groom one another in short bursts (Hart and Hart 1992). Humans engage in both simultaneous (giving with one hand; taking with the other) and sequential forms of reciprocity. It is unclear whether strict or flexible patterns of alternation affect the evolution of reciprocal altruism in nonhuman animals (Dugatkin 1997).

Balance of giving and receiving. In most types of reciprocally altruistic exchanges givers and receivers reverse roles at some point in time. Individuals may give goods or services worth the same as, more than, or less than they receive. In delayed exchanges, individuals may require repayment of the goods or services they proffer to their partners in a particular exchange before engaging in subsequent exchanges, or they may donate two or more times before receiving anything in return. Game theorists have found that generous forms of reciprocal altruism such as Two Tits for One Tat may pay off better than strict Tit for Tat forms of exchange (Nowak 2006). As pointed out by Tooby and Cosmides (1996), it can be in individuals' adaptive interest to give hundreds of small low-cost favors to a dependable recipient in return for one high-value life-saving favor, and we know that humans may be willing to assist friends and loved ones for many years as long-term investments without receiving anything equivalent in return. Some theorists have posited that cognitive abilities such as long-term memory and the ability to keep records of giving and receiving – abilities prominent in the human species – favor the evolution of reciprocal altruism (Hauser et al. 2009).

Costs and Benefits

The value of the goods and services exchanged in systems of reciprocal altruism are reckoned ultimately in terms of contributions to fitness, which often are difficult to document and quantify. Some researchers have suggested that it is especially difficult to assess reciprocal altruism when the goods and services that are exchanged are dissimilar in nature because it tends to be more difficult to determine the fitness value of different currencies than the fitness value of the same currency (Seyfarth and Cheney 1988). However, it also may be difficult to assess the fitness value of similar goods or services because the value of the same item (e.g., an ounce of meat) may depend on the recipient's state (e.g., of hunger), available alternatives, opportunities for better deals, and so on (de Waal and Brosnan 2006). The same principles pertain to the costs of giving.

Gains in Trade

The primary way in which reciprocal exchanges pay off for two or more individuals is through gains in trade. Consider two individuals who possess more goods than they can consume themselves. One individual might possess a large quantity of meat that will soon rot and the other individual might possess a large quantity of fruit. When these individuals engage in an exchange of resources, each can come out ahead because the benefits to both individuals of receiving the goods they need more outweigh the costs of giving the goods they need less. The same principle may apply when individuals trade sex for food ("prostitution") and when individuals exchange the same resource at different points in time. For example, when two vampire bats trade a surplus of blood that they don't need to survive at one point in time for blood that they desperately need to survive at another point in time, they both gain in trade.

Strategies

Evolutionary theorists have assumed that individuals who engage in reciprocal exchanges of goods

and services adopt behavioral strategies (which need not be conscious), and game theorists have played a variety of strategies off against one another in simulations of natural selection to determine which strategies will evolve under particular conditions. The best-known examples are the original games created by Axelrod and Hamilton (1981) using the Prisoner's Dilemma in which the reciprocally altruistic strategy called Tit for Tat won. Subsequent simulations found that more flexibly cooperative strategies that were equipped to ward off unending iterations of selfish exchanges and restart reciprocally altruistic exchanges – strategies such as Tit for Two Tats, Generous Tit for Tat, Contrite Tit for Tat, Win-stay, Lose switch, and Firm but Fair could defeat strict Tit for Tat strategies and evolve (Nowak 2006). This research demonstrated that in order for reciprocally altruistic strategies to defeat other strategies, they must be conditional, discriminating, and resistant to cheating. Follow-up research found that more than one strategy may evolve and become evolutionarily stable in some populations, that strategies may fluctuate in populations in frequency-dependent ways, that the ability to discriminate between cooperative and uncooperative members of groups and the ability to identify, avoid, and punish cheaters can facilitate the evolution of reciprocally altruistic strategies.

Direct and Indirect Returns To sustain reciprocal altruism, helping another individual must somehow contribute to the helper's fitness. In nonhuman animals, the return benefits are usually proffered by the recipient of the altruistic overtures. The exchanges that occur in food-sharing and grooming constitute examples. This type of reciprocal altruism is referred to as direct or concrete reciprocity. However, in other cases – notably prominent in the human species – the return benefits may stem from other sources, especially third parties from the helper's group. This type of reciprocal altruism has been labeled indirect reciprocity (Alexander 1987). There are at least four forms of indirect reciprocity. In the first form, one individual helps a second individual who helps a third individual who, in turn, helps the first individual in a daisy chain-like sequence. In the

second form, one individual helps another individual who returns the favor, and a third individual initiates a reciprocal exchange with the individual who returned the favor. In the third form, individuals contribute to some central source that redistributes the goods and services, and in the final form, individuals contribute to groups whose existence increases their survival and reproductive success. In systems of indirect reciprocity, what goes around comes around with dividends through third parties.

Indirect reciprocity may enable participants to reap greater gains in fitness than direct reciprocity can, because the former is equipped to produce greater gains in trade than the latter. Alexander (1987) suggested that systems of indirect reciprocity evolved in the human species because early humans living in hunter-gather groups were able to increase their fitness by initiating exchanges with members of their groups whom they observed behaving altruistically and cooperatively and/or with members of their groups with a reputation for being reliable and generous exchange partners. Alexander also suggested that altruistic and cooperative members of groups could benefit genetically from the increased fitness of their collateral relatives that their altruism and cooperation produced, and from the increased success of their groups.

Antidotes to Cheating

The central reason that reciprocal altruism is not more prevalent in the animal kingdom probably stems from the vulnerability of systems of reciprocity to cheating and free-riding. To evolve, adaptations mediating reciprocal altruism must be equipped to withstand the exploitation of those who either take without giving in return – a phenomenon dubbed “gross cheating” by Trivers – or take more than their share and give less – a phenomenon labeled “subtle cheating” (Trivers 1971, p. 46). When individuals are grossly cheated, they suffer the costs of giving without any compensatory benefits. Although individuals who are subtly cheated obtain benefits, they benefit less than their partners. Krebs (2011) has

characterized the susceptibility of systems of reciprocal altruism and other forms of cooperation to cheating and free-riding as a “tragic irony,” because, in favorable conditions, if everyone cooperated, everyone could reap copious gains in trade without suffering the costs of guarding against free-riding and punishing cheaters. In contrast, if everyone behaved selfishly, cheated, and attempted to free-ride, no one would reap the fruits of cooperation.

Adaptations to cheat and adaptations to counteract cheating would be expected to evolve in an arms race manner. In direct forms of reciprocity, individuals can avoid being cheated by exchanging goods or services simultaneously, in effect giving with one hand and taking with the other. In delayed forms of direct reciprocity, individuals can guard against cheating or minimize its negative effects by demanding reciprocation soon after making relatively small donations, by making additional giving contingent on receiving a fair return (such as, for example, in tit for tat type strategies), by threatening or punishing cheaters, and by rejecting cheaters as future partners and ostracizing them from groups.

Systems of indirect reciprocity tend to be more vulnerable to cheating than systems of direct reciprocity are, because it usually is easier to identify those who fail to pay you back than to identify those who fail to pay third parties back, and the biological and genetic benefits of punishing individuals who have cheated others do not tend to be as great as the benefits of punishing individuals who have cheated you.

Inasmuch as punishing cheaters entails a cost, how could it be in the adaptive interest of individuals to punish third parties who have cheated others (a phenomenon that has been labeled “altruistic punishment”)? The main answers to this question offered by evolutionary biologists are (a) punishing third party cheaters may benefit one’s relatives; (b) punishing third party cheaters may help one’s group function more effectively, which in turn may produce collateral benefits for the punishers; (c) some forms of punishment, such as avoiding and shunning those who have cheated others or those who have a reputation for being cheaters, proffer direct benefits to those who

employ them; and (d) individuals may reap indirect benefits by acquiring a reputation as someone who is willing to suffer the costs of punishing third party cheaters (see Alexander 1987). On the other side of the coin, cheaters may suffer losses in fitness (a) through rejection as a partner by third parties who have observed them cheating, (b) through losses in status, (c) through ostracism, and (d) through negative effects on the group that filter back to cheaters and their relatives. In groups practicing indirect reciprocity, we would expect members to be vigilant for cheating and free-riding, to gossip about the social behaviors of others, and to be concerned about their reputations and the reputations of others. Alexander (1987) suggested that the problem of cheating in indirect systems of reciprocity can be solved if members of groups interact with others in a selective manner, favoring cooperators and discriminating against cheaters.

Studies from several areas have supported Alexander's (1987) theory of the evolution of indirect reciprocity. Game theorists such as Nowak and Sigmund (1998) have found that systems of indirect reciprocity can evolve when members of groups tag others with positive or negative images ("image scoring"), depending on whether they are seen to behave altruistically or selfishly toward third parties, and favor those with positive images. Psychologists have found that people's willingness to cooperate increases when they are in public and when they expect cooperation to enhance their reputations (Barclay 2004). Anthropologists have found that members of small societies who contribute more than their share to communal projects, who behave in ways that promote the public good, and who are courageous in battle, are sought out as partners more frequently than their fellows (Hawkes 1983). And economists studying large business firms have found that the social status of employees is positively correlated with their perceived generosity (Flynn 2003).

Although the individuals who participate in systems of indirect reciprocity behave in immediately altruistic ways, the mental mechanisms that induce them to behave in these ways evolved because they increased their long-term fitness,

and this renders the behaviors biologically selfish. Systems of indirect reciprocity evolve because they produce return benefits for those who participate in them. Evolutionary theorists expect people to be tempted to exploit systems of indirect reciprocity and to manipulate others into behaving in ways that increase their fitness. As expressed by Alexander (1987), "the long-term existence of complex patterns of indirect reciprocity may be seen as favoring the evolution of keen abilities, first, to make one's self seem more altruistic than is the case and, second, to influence others to be altruistic in such fashions as to be deleterious to themselves and beneficial to the moralizer, for example to lead others to invest too much, invest wrongly in the moralizer or his relatives and friends, or invest indiscriminately on a larger scale than would otherwise be the case. Thus, individuals are expected to parade the ideas of much altruism and of indiscriminate altruism as beneficial, so as to encourage people in general to engage in increasing amounts of social investment whether or not it is beneficial to their interests. They may be expected to locate and exploit avenues of genetic relatedness leading to nepotistic flows of benefits. They may also be expected to depress the fitness of competitors by identifying them, deceptively or not, as reciprocity cheaters; to internalize rules or evolve the ability to acquire a conscience...and to self-deceive and display false sincerity as defenses against detection of cheating and attributions of deliberateness in cheating" (p. 190).

Group Contexts

Characteristics of groups may constitute significant ingredients in the evolution of reciprocal altruism. Among these characteristics, those that pertain to the probability of reciprocal altruists encountering other cooperators, and those that pertain to the probability of selfish individuals encountering other selfish individuals are probably the most important. Cooperative and selfish individuals may be distributed in different ways within relatively large groups. The higher the probability of an individual who is disposed to

engage in reciprocal altruism encountering another cooperative individual, the greater the payoff for reciprocal altruism will be. In the extreme case, reciprocal altruism could pay off well for all members of groups consisting entirely of reciprocal altruists. When reciprocal altruists are able to identify one another and differentiate themselves from cheaters (in whose interest it will be to mimic them), they may seek one another out, form subgroups, and exclude selfish individuals from their cooperative groups. Assortment of cooperating and cheating individuals favors the evolution of reciprocal altruism (Dugatkin 1997). In large groups, constraints on members' opportunity to "rove" and interact with new partners favors the evolution of reciprocal altruism because it enables reciprocal altruists to discriminate against cheaters and favor cooperators (Dugatkin 1997).

It is generally agreed that small groups favor the evolution of reciprocal altruism. Indeed, theorists such as Boyd and Richerson (1992) have asserted that reciprocal altruism cannot evolve in large groups. However, Trivers (2006) has questioned this conclusion, pointing out that it is based on the assumption that if a selfish (or "defecting") member of a group decides to cooperate, every other member of the group must benefit. Trivers insists that the costs and benefits of most incidents of reciprocal altruism are confined to the individuals involved in the exchange.

The Origin of Adaptations for Reciprocal Altruism

Evolutionary theorists have offered two main explanations for the origin of systems of reciprocal altruism. First, they have suggested that such systems could grow out of reciprocal exchanges supported by kin-selected adaptations (Axelrod and Hamilton 1981). For example, adaptations for blood-regurgitation by vampire bats, which surely originated as a way for mothers to feed their young, may have generalized to collateral kin, then to nonkin. Second, systems of reciprocal altruism could have originated in low-cost

exchanges that increased in value as participating individuals experienced gains in trade and acquired confidence in the relationship (Roberts and Sherratt 1988).

Proximate Mechanisms

Such theorists as Hauser et al. (2009) have attributed the dearth of documented cases of reciprocal altruism among nonhuman animals to the absence in most species of the cognitive abilities necessary to engage in calculated forms of reciprocal altruism – abilities that enable animals to discriminate between reciprocally altruistic and nonaltruistic members of their groups, remember who has helped them and cheated them over relatively long periods of time, quantify costs and benefits, detect inequities, delay gratification, and distinguish between intentional and accidental behavior. However, as pointed out by other theorists, the sophisticated record-keeping abilities that enable animals to engage in calculated forms of reciprocal altruism are not necessary for all forms of reciprocal altruism (de Waal and Brosnan 2006). Many other adaptations, such as those that give rise to such emotional reactions as love, sympathy, gratitude, guilt, forgiveness, vindictiveness, righteous indignation, and the desire to reconcile, could support reciprocally altruistic relations (Trivers 2006).

Conclusion

In 1971, Trivers introduced the concept of reciprocal altruism to explain how mutually beneficial exchanges between nonrelatives could evolve. The main ingredients of reciprocal altruism are (a) exchange partners, (b) goods and services, (c) giving and receiving, (d) costs and benefits, (e) gains in trade, (f) strategies, (g) direct and indirect returns, (h) antidotes to cheating, and (i) group contexts. The central problem that animals seeking to benefit from the gains in trade they can obtain from reciprocal exchanges must solve – and therefore the central obstacle to the evolution of reciprocal altruism – is the temptation

for exchange partners to cheat, either by taking without giving in return, or by taking more than they give in return. Game theorists have identified strategies that are equipped to solve this problem. Adaptations for reciprocal altruism probably evolved from kin-selected adaptations for altruism and as extensions of low-cost exchanges. Although reciprocal altruism is prevalent in the human species, it is relatively rare in the rest of the animal kingdom.

Definition

The evolution of the cognitive architecture humans use to sort themselves into coalitions of us versus them.

Introduction

Considerable attention across the social sciences has been paid to understanding how people categorize individuals into groups and create group identities. Throughout human history, conflict between groups was founded on categorizing relationships into “us” and “them” and social psychologists have long recognized the importance of group membership to human social organization. The “minimal group paradigm,” established as a method for investigating the minimal conditions required for discrimination to occur between groups, has continued to show that even virtually meaningless distinctions between groups, such as shirt color, can trigger a tendency to favor one’s own group over others. It is clear that the ability to readily distinguish between in-groups and out-groups played a key role in our evolutionary history.

Kinship

Understanding the potency of human group identification is often constructed around theories of kin selection – favoring one’s genetic relatives at a cost to one’s own survival and reproduction (Hamilton 1964). If ancestral human groups were composed primarily of closely related individuals, then a shared culture, background, or belief system may have served as a reliable phenotypic marker of genetic relatedness (Swann et al. 2014), and kinship may therefore have played an important role in building the cognitive architecture employed in group identification and formation. Anthropological studies of group fissioning along kin-lines, such as occurred within Yanomamo tribes of the Amazon, confirm this prediction. A cross-cultural study of 32 hunter gatherer groups, however, suggests that kinship may be overstated by evolutionary psychologists and that inclusive fitness (Hamilton 1964) – the ability of an individual organism to transfer genes to the next generation either directly through offspring or indirectly through the offspring of close relatives – cannot explain the composition and cooperation of hunter gatherer social structures. For example, close kin (e.g., siblings, spouses, parents) often make up less than 10% of a residential group and in some groups like the Ache of Paraguay, the mean genetic coefficient of relatedness (r) between adults was estimated to be 0.054 suggesting that kinship may not fully explain group cohesion (Hill et al. 2011).

Kin Psychology

Regardless of the average relatedness of early human groups, many explanations of self-sacrifice for a large group of unrelated individuals are built on kin selection and rely on something called “kin psychology” – forming kinship like bonds with unrelated individuals. These types of explanations tend to focus on cultural adaptations which harness cognitive mechanisms that direct our interactions with genetic relatives. For example, researchers have suggested that applying kinship terminology to a group of close friends

(e.g., a band of brothers) or a nation (e.g., “the motherland”) can trigger emotional responses that are similar to those activated by kin selection. Building on these ideas, Whitehouse (2018) developed the theory of “identity fusion,” arguing that extreme self-sacrifice results when individuals align their own identity with that of the group through bonding over intense shared experiences (e.g., the horrors of war) or from perceptions of shared biology (e.g., recognizing putative kin by looking for individuals with similar traits called “phenotypic matching”). As a result, certain social connections might enable one to view others with such shared experiences or traits as kin. Interestingly, identity fusion is expected to be particularly powerful when combined with a strong outgroup threat. Together, these theoretical arguments and empirical results suggest that extreme self-sacrifice is made possible by exploiting psychological pathways dedicated to kin-biased altruism.

Parochial Altruism

A long history of lethal between-group competition is also likely to have played an important role in generating attitudes towards in-groups and out-groups in humans and Bowles theorized that these biases depend on the frequency of conflict between rival bands in the evolutionary past. The willingness to sacrifice for an in-group, combined with out-group hostility, has been called “parochial altruism” and this phenomenon may help to explain why clear boundaries between human groups are so pervasive. Using simulations, Choi and Bowles (2007) found that groups whose members are hostile towards other groups and are altruistic towards their own groups are more likely to succeed when the frequency of lethal intergroup conflict is high.

Phenotypic Matching and Strategic Coalitions

What cues do humans use to infer shared genes (i.e., phenotypic matching), beliefs, or interests

(i.e., shared experiences) and thereby create boundaries between in and out-groups? There is considerable evidence that when being asked to remember an unknown person, humans are automatically able to remember three “primary” traits – sex, age, and race. Hirschfeld (1998) argued that categorizing individuals by their race is a byproduct of essentialism – the idea that every organism has a set of qualities that forms their identity – and evolved due to our need to reason about natural types, and Gil-White (2001) has suggested that humans process racial and ethnic groups like species. Some ethnographies provide tentative support for this sort of essentialist thinking. For example, the name Yānomamö that a group of horticulturalists living in the Amazon rainforest call themselves is often translated as “human beings” and other enemy tribes or non-Yanomamo groups are not considered to be human. Other researchers see in-group biases as evolving to reap the advantages derived from forming and being a member of a coalition. Here, categorizing people by their race is viewed as byproduct of cognitive structures that evolved to detect coalitional alliances. The likelihood that humans would rarely, if ever, have traveled far enough to have encountered individuals from a population different enough to qualify as a race lends support for this view. Both essentialism based on shared beliefs or ancestry and the ability to form flexible strategic coalitions based on shared interests are likely to play an important role in human group affiliation, however.

Religion

Humans also form coalitions around shared beliefs, and religion has the ability to redraw boundaries between groups and create group identities. Indeed, several studies have suggested that a key function of religion is to bind individuals into groups, and members of religious groups often favor individuals who share their faith. Furthermore, religions frequently have specific rules that promote the defense of their group while simultaneously propagating hatred of out-

groups. In a Jamaican sample, hostility towards out-groups was positively predicted by extrinsic religiosity (i.e., using religion to achieve non-religious goals) but negatively associated with religious devotion (e.g., belief in God) (Lynch et al. 2017).

Political Beliefs

Although religious beliefs, race, sex, ethnicity, and age are some of the most salient cues humans use to categorize other people into groups, other cues may also be relied on as a reflection of an individual's beliefs. For example, in recent years, political views have often been used to assess group membership. In 1960, a poll found that 5% of Republicans and 4% of Democrats would "be unhappy" if their child married someone from the opposing party. In 2010, half of Republicans and a third of Democrats surveyed reported that they would be either "somewhat upset" or "very upset" if this happened. Today, implicit association tests (which measure how quickly people categorize positive and negative words with groups) have shown that people show greater prejudices against political foes than those of different races or religions.

Humor and Laughter

Laughter and sense of humor are also frequently used to categorize individuals into groups. For example, laugh tracks amplify real human-generated laughter only when individuals believe it comes from members of an in-group. This suggests that laughter may function to reinforce within group social bonds. People also report liking others who laugh at their jokes and share their sense of humor, and laughter is more common in the presence of others, especially friends, which suggests that it may be connected to both social bonding and communication. Sharing a sense of humor has also been shown to be extremely important in mate selection and sense of humor may help to assess in-group status or potential mates by determining when others share

our unconscious biases and beliefs (Lynch and Trivers 2012; Lynch 2010).

Conclusion

The formation of boundaries between human groups and groupish behavior can be understood within an evolutionary framework. In general, it is thought that a decreased trust of unknown individuals and groups would have provided fitness advantages to our ancestors and helped to protect them and their offspring from risks posed by other humans. If this interpretation is correct, then we should expect that cognitive structures specifically designed to quickly categorize people into "us" and "them" would have been targeted by natural selection. Although many of the mechanisms remain unclear, such as whether in-group loyalty and outgroup hate are linked, an evolutionary viewpoint provides a functional explanation for why these biases are so fundamental to human behavior.

In-Group–Out-Group Bias

Alexander Shkurko

Ulyanovsk/Nizhny Novgorod, Russia

Synonyms

[Intergroup bias](#); [Social bias](#)

Definition

A tendency to react differently and asymmetrically toward others, depending on whether they are from the in-group (to which an individual belongs) or from the out-group.

Introduction

Unlike other species, humans live in large and complex social groups, which are based on numerous and diverse social relations, extended cooperation, and cultural norms. To deal with this “ultra-sociality” (Tomasello 2014), humans needed advanced and specialized skills to accurately represent the complex social structure, identify and regulate social relations, predict others’ behaviors, and develop own behavioral strategies. The foundation of such abilities is social categorization, i.e., perception and representation of others in terms of their group membership and common, typical traits. Social categorization helps to reduce the complexity of social environment by applying a limited set of rules to unlimited number of social agents.

The simplest and basic form of social categorization is a binary distinction between a group and category, to which an individual belongs (in-group) and other groups (out-groups). Although there are many types of social groups, identified on the basis of various criteria (kinship, race, ethnicity, age, gender, profession, political attitudes, language, class, etc.), the basic in-group/out-group opposition can be applied in any case. As the evolution of human societies relied

significantly on the combination of intragroup cooperation and intergroup competition, the in-group/out-group categorization became a basis of a wide range of asymmetrical reactions to other people, depending on their identified in- or out-group status.

Types and Effects of Intergroup Bias

In studying asymmetrical reactions to others as a function of their group membership, social psychologists use several terms, often interchangeable: bias, prejudice, stereotype, and discrimination. Among them, the term “bias” is the least univocal. By prejudice, researchers mean specific attitudes toward groups and their members. Typically, in-group members are evaluated more positively and elicit more positive emotions. Stereotypes are specific sets of traits and characteristics associated with particular group. For example, in-group members are often considered as more trustworthy, whereas out-group members can be perceived as more aggressive. Discrimination refers to overt behavior, depended on group membership. People typically make unfair decisions in favor of their in-groups, for example, distribute more resources to them.

As regards the term “bias,” its definition is not so clear. Often researchers use it as a general concept embarrassing various types of group-based asymmetries in cognitive, affective, or behavioral domains. For example, John Dovidio and other authors of *The SAGE Handbook of Prejudice, Stereotyping and Discrimination* define intergroup bias as “the systematic tendency to evaluate one’s own membership group (the ingroup) or its members more favorably than a non-membership group (the outgroup) or its members” (Dovidio et al. 2010, 3) and see it as encompassing prejudices, stereotypes, and discrimination. Although such or similar definitions are widespread, they are problematic in at least two aspects.

First, evaluation is only one type of group-based asymmetrical responses, and there are other processes, which are known to be regulated by the in-group/out-group distinction. For

example, intergroup biases in such basic cognitive processes as attention and memory are well-documented (e.g., Kawakami et al. 2014; Meissner and Brigham 2001). They cannot be described as evaluative biases and are neither prejudices, nor stereotypes, nor discrimination.

Second, it implies that intergroup bias is always a kind of an *advantage* and, moreover, an advantage in favor of the in-group. This is however not necessarily so. For example, a well-documented tendency to pay more attention to in-group members or to remember them better can hardly be called an advantage. Rather, it reflects the difference in the perceived or expected significance of social information. If the evolution of humans was primary directed by the needs for within-group cooperation, greater vigilance to any in-group-related information is explainable. The preference for in-group is also not always the case and can be reversed by other factors, and especially social status, so that a high-status out-group is preferred as compared to the in-group (e.g., Rudman et al. 2002; Newheiser et al. 2014).

For these reasons, it is more accurate to describe intergroup bias as a wide range of asymmetrical reactions to members of various social groups and to in-/out-groups at the most general level. Social categorization, even in its simplest form of in-/out-group distinction, underlies asymmetrical reactions in a wide range of psychological and behavioral processes: perception, memory attention, evaluation, judgments, emotions, decision-making, and approach-avoidance behavior. Intergroup bias was documented in respect to many different types of social groups and categories: racial, ethnic, gender, age, political, religious, etc. The fact that intergroup bias was found even in the so-called “minimal” groups (in-/out-groups defined according to an arbitrary, situational criterion, which exist only during an experiment) confirms that the tendency to respond differently to various groups is deeply rooted in human mind. Studies in cognitive and neuroscience demonstrated that many types of bias are implicit and can be evoked automatically and unintentionally. Further, intergroup bias and preference for own group are common in primates and other animals. Thus, there is strong evidence that the diversity

and strength of intergroup bias effects have evolved to support the specific needs of social life and, particularly, within-group cooperation. At the same time, effects of intergroup bias in specific contexts can vary and depend on many intermediate factors such as personal goals and motivation, familiarity and the history of intergroup contact, time course of social information processing, availability of alternative social information, social norms, etc.

Conclusion

Social categorization is the foundational ability necessary to represent and navigate the social complexity of human societies. Even the simplest and basic social categorization, i.e., in-group–out-group distinction, has a profound impact on human cognition, emotions, attitudes, and behavior. The differentiation between “Us” and “Them” triggers cognitive mechanisms supporting, in a normal situation, preferential processing of in-group-related information and emotional and behavioral predispositions in favor of the in-group. These mechanisms provide the basis for cooperation and affiliative relations, which are crucial for social life and survival of human groups. At the same time, they underlie a wide range of problems in intergroup relations varying from subtle symbolic discrimination to overt and aggressive conflicts.

Definition

The process of suppressing an automatic/prepotent response or mental representation.

Introduction

Inhibition is an executive function that serves to reduce behavioral or cognitive activity, either consciously or unconsciously. Whereas behavioral inhibition refers to the suppression of a prepotent motor response (i.e., any response associated with a history of positive or negative reinforcement), cognitive inhibition refers to the suppression of mental processes. Inhibition may involve the complete cessation of a behavior or mental process, the slowing down of a behavior or mental process, or a decrease in the probability that a behavior or mental process will occur.

Behavioral Inhibition

Behavioral inhibition refers to the process of inhibiting prepotent responses, delaying immediate, ongoing responses, and preventing extraneous information from interfering with response processes (Logan and Cowan 1984). Logan and Cowan (1984) seminal horse race model suggests behavioral inhibition depends on the relative completion times of independent go and stop processes that are initiated by prepotent stimuli and stop signals, respectively. Inhibition occurs when the go process (i.e., prepotent response) is unable to overcome the stop process. Deficits in behavioral inhibition are theorized to be upstream of deficits in other executive functions, such as working memory and self-regulation, which lead to impaired motor control (Barkley 1997).

Behavioral inhibition has been examined using several paradigms in experimental research. The go/no-go (GNG) paradigm (Donders 1969), for example, has been used to examine internalized, automatic responses to stop signals, while the stop signal (SS) paradigm has been used to examine behavioral inhibition within the context of more complex cognitive processes (Verbruggen and Logan 2009). GNG and SS tasks are similar such that they both require individuals to respond to go stimuli that are presented successively across go-response trials and inhibit responses to no-go/stop stimuli (e.g., an auditory tone) that are typically presented during approximately 25–33% of experimental trials (Alderson et al. 2007). However, whereas the GNG paradigm presents intermittent stop trials in context of a simple reaction time go-task, the go-task of the SS paradigm is a choice reaction time task. As such, the GNG task is deemed more suitable for the examination of inhibition processes involved in automatic prepotent responses, while the SS task may be more appropriate for the examination of speed/accuracy trade-offs and attention processes associated with inhibition. Examples of other behavioral inhibition paradigms include antisaccade tasks, delay-of-gratification tasks, flanker tasks, and the Simon task.

Cognitive Inhibition

Cognitive inhibition refers to the process of inhibiting prepotent mental representations associated with an external stimulus or internal thought (Dagenbach and Carr 1994). This process involves blocking and/or removing irrelevant information from working memory or preventing attention from being directed to information that has been previously rejected. Cognitive inhibition includes reducing extraneous information access to attention as a whole, as well as reducing attention to specific psychological pathways (Dagenbach and Carr 1994). For example, when a child ignores what is happening outside their classroom window so that they may instead attend to a teacher's lesson, they are using cognitive inhibitory processes to direct their external focus of attention away from irrelevant external stimuli. Similarly, cognitive inhibition is involved when a child directs their internal focus of attention to class-related information rather than daydreaming (Dempster and Brainerd 1995).

Cognitive inhibition has been examined extensively using the Stroop Color-Word Task. This task involves reading a word and indicating the color in which the text is written while ignoring the content of the text (MacLeod 1991). For example, the correct response to the word *red* presented in green font would be *green*. A prototypical task compares average reaction times obtained from compatible (word meaning and font color are the same) and incompatible (word meaning and font color are different) trials, with slower reaction times during incompatible trials, relative to compatible trials, providing evidence of increased demands on cognitive inhibition. That is, incompatible trials require participants to inhibit the text's meaning that is irrelevant to accurate task completion. A variant of this procedure administers a control condition that presents swatches of color and asks participants to correctly name the color (MacLeod 1991). The task was originally designed to measure interference or reduced performance when conditions contain multiple distracting stimuli but is now used more frequently as a measure of inhibition (Dempster and Brainerd 1995). Additional

common examples of cognitive inhibition paradigms include singleton distractor tasks and directed forgetting tasks.

Inhibition in Psychopathology

Deficits in inhibition have been implicated in the development and maintenance of psychopathology. Deficits of motor control (i.e., behavioral disinhibition), for example, are predominantly associated with disorders related to poor impulse-control and self-regulation, such as attention-deficit/hyperactivity disorder (Alderson et al. 2007; Patros et al. 2016). In contrast, deficits of cognitive control (i.e., cognitive disinhibition) are predominantly associated with disorders related to distorted mental representations of internal and external stimuli, such as anxiety and depression (Clark and Beck 2010).

Conclusion

Collectively, inhibition refers to any mechanism by which an individual intentionally or unintentionally suppresses behavioral or cognitive activity. Inhibition is assessed using cognitive or behavioral tasks that require an individual to withhold, delay, or cease responding while resisting distraction of competing events (i.e., interference control). Deficits in inhibition are highly associated with deficits in other executive functions, such as working memory and self-control, and play a large role in the development of psychopathology among children and adults, including ADHD, mood disorders, anxiety disorders, substance use disorders, and psychotic disorders.

Innate and Learned Tool Use

Ivo Jacobs and Mathias Osvath
Lund University, Lund, Sweden

Definition

Innate tool use normally means that it is a highly heritable evolved adaptation, found in at least one age-sex class, or not learned.

Introduction

The concept of innateness is surrounded by controversy. Some claim it is a meaningful notion, while others argue it has no explanatory power. Innateness is commonly pitted against learning, but definitions vary widely. There are at least nine different meanings of innate: “present at birth or particular stage of development; not learned; genetic – highly heritable; adapted during evolution; develops before function is established; shared by all members of species/sex/age group; a functional behavioral system; controlled by a specialized neural module; and developmentally robust – well-canalized” (Bateson and Curley 2013). For the sake of clarity, it is therefore more appropriate to talk about specific meanings than innateness in general.

Tool use in nonhuman animals has often been described as either innate or learned, but a deeper distinction is necessary for meaningful discussion.

Here we discuss the most commonly used meanings of innate tool use, which we compare with the possibility of learning. Following Shumaker et al. (2011), tool use is defined as “the external employment of an unattached or manipulable attached environmental object to alter more efficiently the form, position, or condition of another object, another organism, or the user itself, when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool.”

Is Tool Use Found in at Least One Age-Sex Class?

Tool use is customary when it is present in at least one age-sex class of the species. Although the exact criteria vary, tool use appears to be customary in (some populations of) chimpanzees, orangutans, bearded capuchin monkeys, Burmese long-tailed macaques, California sea otters, bottlenose dolphins, Egyptian vultures, brown-headed nuthatches, New Caledonian crows, Hawaiian crows, woodpecker finches, satin bowerbirds, green-backed herons, and archerfish (Hunt et al. 2013; Meulman et al. 2013; Rutz et al. 2016; Shumaker et al. 2011; Tebbich and Teschke 2013). Customary tool use might be more prevalent in invertebrates, although it is not often investigated as such. For example, hermit crabs use shells for protection, worm lions throw sand to capture prey, digger wasps use object to compact the soil around their burrows, leaf beetle larvae use physical and chemical shields for protection, boxer crabs use anemones to catch food debris, bolas spiders throw sticky bolas to catch prey, and octopuses throw sand over their bodies for camouflage (Shumaker et al. 2011).

However, customary tool use in some vertebrate species is a product of social learning. The frequency of certain tool modes in different populations is often monitored in studies on their cultural transmission. A tool behavior is usually said to be cultural if it is only found in some populations and if this variation cannot be explained by ecological or genetic factors (Meulman et al. 2013).

In contrast, tool use in invertebrates is often widespread within the species or genus, arises from little to no social contact, is highly context specific, involves relatively little working memory, and is only rarely innovated. Such tool use is therefore called stereotypic, which bears many similarities with innateness and instinct because learning plays only a minor role (Hunt et al. 2013). There is notable variation within the aforementioned vertebrates too. Flexible tool use typically develops later in ontogeny, through a more error-prone process, and involves different types of social transmission. Nonetheless, such learning may be supplemented by inherited behavioral predispositions that scaffold tool use, such as object manipulation and exploration (Meulman et al. 2013). Thus, although tool use in many species is found in at least one age-sex class, this does not directly oppose learning.

Is Tool Use Highly Heritable?

Heritability is the proportion of total phenotypic variation that is attributable to genetic variation (Hopkins et al. 2014). Intelligence as measured by IQ is heritable in humans in the sense that it has a strong genetic component, but it is also influenced by environmental factors. Similar results based on a cognitive test battery have been found in chimpanzees. Individual score was stable when tested again 2 years later, and sex and rearing history played only a minor role (Hopkins et al. 2014). Of all 13 tasks the highest heritability score was for tool use, which was passed if the subject could retrieve out-of-reach food with a stick within 2 min. It also had the highest phenotypic variability, so the ability to use tools appears to be strongly influenced not only by genetics but also individual experience. Tool use had the largest variability in studies comparing primate species, which suggests the findings in chimpanzees could be similar for other primates, and that tool use strongly affected primate evolution (Woodley of Menie et al. 2015).

However, this notion of heritability is simplistic because it overlooks the complex interactions between genes and environment. The heritability

ratio is not an absolute quantity but depends on many factors, such as the population, rearing history, and test circumstances. Moreover, heritability does not necessarily oppose learning. For example, walking on two legs is a fundamental property of being human, but it requires extensive learning nonetheless (Bateson and Curley 2013).

Is Tool Use an Evolved Adaptation?

Tool use is likely to be adaptive if it contributes significantly to daily food intake. Woodpecker finches from the Galápagos Islands use sticks and cactus spines to extract invertebrates from tree holes and crevices. The prevalence of this tool use varies strongly between areas and seasons. They rarely use tools in a stable zone with more abundant prey. In the dry zone, they use tools for 12 % of the foraging time during the wet season and nearly 50 % during the dry season. Tool use enables them to obtain prey that otherwise would be inaccessible, and although it takes longer to extract them, they are larger and more energy rich than other prey types. It allows these finches to change their foraging style between habitats and seasons. In contrast, the closely related large tree finch has evolved a powerful beak to extract arthropods. This morphological adaptation limits pecking and probing and is associated with niche specialization, whereas the tool use by woodpecker finches is a temporary solution that allows for more foraging flexibility. It develops through individual learning and does not require social input. Young finches learn to use tools whether they come from the stable or dry zone, which suggests that a genetic predisposition develops into tool use if it is learned during a sensitive ontogenetic phase (Tebich and Teschke 2013).

New Caledonian crows also use tools for extractive foraging on remote islands. Among others, they use sticks to extract fat-rich larvae from wood. Three larvae are sufficient for a crow's daily energy intake, and on average they consume 1.8 larvae per day. Tool use is thus responsible for a substantial proportion of their foraging ecology. However, these larvae are not always available across the crows' distribution, and the ecological significance of their other tool

use remains largely unknown. Similar to woodpecker finches, New Caledonian crows develop tool use in the absence of demonstrators but with individual practice. However, tutored crows handle and insert twigs more often than untutored crows (Rutz and St Clair 2012).

Hawaiian crows, which are only distantly related to New Caledonian crows, were recently discovered to also use sticks to extract food from logs. Although they are extinct in the wild, tool use seems to be part of their natural behavioral repertoire because most captive individuals use tools and juveniles develop this ability without training or social input. Determining the importance of tool use in their foraging ecology can only be done in wild populations, but its species-wide occurrence suggests it is an evolved adaptation (Rutz et al. 2016). Tool use is similarly widespread in some other species, notably invertebrates (Hunt et al. 2013; Shumaker et al. 2011).

Morphological adaptations to tool use can also show its impact on the evolution of a species. Similar to an aye-aye using its elongated digit or a woodpecker its elongated tongue, chimpanzees, woodpecker finches, and New Caledonian crows use sticks to extract wood-living prey. These are different adaptive solutions to the same ecological problem of extractive foraging. Human hands enable dexterous manipulation, and tool use seems to have played a large role in their evolution, although this cannot be directly determined. New Caledonian crows also appear to have several morphological adaptations to or predispositions for tool use. Compared to other crow species, they have a wide binocular overlap, and their beak is relatively strong and straight, which allows them to monitor the working tool tip during probing. This strongly suggests that at least some of these features evolved for improved tool manipulation (Matsui et al. 2016). Hawaiian crows might have independently evolved similar morphological features (Rutz et al. 2016).

Conclusion

The question of whether tool use is innate or learned can only be answered by deconstructing

what is meant by innateness (Bateson and Curley 2013). Many species use tools and most meanings of innateness have never been directly investigated, so a clear answer is impossible at this time. Currently tool use seems to be both innate and learned with varying degrees depending on species, and this answer is unlikely to change when asked as an absolute question. The link between genes and behavior is long, and learning itself has genetic components. Nonetheless, research continues to address some of these issues and has revealed that some species have widespread tool use, have morphological adaptations to tool use, strongly rely on tools for daily energy intake, and partially inherit tool-using skills. Ultimately, the deconstructed meanings of innateness will prove to be useful in understanding tool use in the animal kingdom.

Inner Ear, The

Michael Khalil
University of Nicosia, Nicosia, Cyprus

Synonyms

[Balance system](#); [Cochlea](#); [Vestibular system](#)

Definition

One of the three parts of the ear where the cochlea and the balance system is contained.

Introduction

The inner ear is responsible for the analysis of sound, since it contains the cochlea, the most significant structure of the inner ear responsible for the analysis of sound. The inner part of the ear contains the vestibular system responsible for balance and movement.

The Physiology of the Inner Ear

The physiology of the inner ear is consisted of the cochlea and the balance system (the vestibular system). It is notable that the human cochlea and the cochlea of other mammals were firstly discovered in 1561 (von Bekesy 1948) and resonance, as the foundation of the perception of sounds, was proposed by Duverney in 1683 (Mudry 2000) after observing the phenomenon of the resonance of two strings in tune with each other in the musical instrument Piano during the seventeenth century (von Bekesy 1948). Based on Johnsson and Hawkins (1967), our understanding of the structure of the inner ear is based on the work of many researchers who are associated with specific cochlear cells. Of particular reference were the detailed drawings of Magnus Gustaf Retzius (Jelliffe 1920) of the cytoarchitecture of the human organ of Corti, depicting the membranous labyrinth and its parts, cross sections of the cochlear duct, and surface preparations of the organ of Corti on different developmental stages of humans (Johnsson and Hawkins 1967).

The Cochlea

The cochlea has a shape like a snail and contains fluid compartments in a spiral form. The organ of Corti is contained there, one of the main structures responsible for the analysis of sound waves. There

are more than 15,000 hair cells in each cochlea, and are stimulated by the vibrations of the inner ear fluid – its movement producing electrical signals perceived as hearing from the brain (Balkany and Brown 2017). The cochlea is also responsible for separating the sounds based on frequency (Moller 2013).

The Vestibular System

The vestibular system is comprised of the vestibule, which is the space shared by the cochlea and the semicircular canals. The osseous labyrinth or bony labyrinth is made up by the cochlea, the vestibule, and the semicircular canals. In the osseous labyrinth rests a structure called membranous labyrinth, which can be thought of as a sac filled with fluid. The movement of the fluid in the semicircular canals is pushed on a structure called the cupula, which consists of hair cells that transduce the mechanical movement into electrical signals in the brain (Boulpaep and Boron 2005). Each inner ear has three semicircular canals, a utricle, and a saccule (Balkany and Brown 2017).

Conclusion

The physiology and function of the structures of the inner ear were briefly reviewed. These include the cochlea and the vestibular system.

Bodily and Physical Cues

Women's attractiveness indexes health, fecundity and successful mothering potential (the ability to most successfully raise offspring independent of the ability to become pregnant), femininity,

and pathogen resistance (Buss and Schmitt 1993; Cunningham 1986; Cunningham et al. 1990, 1995; Henss 1992, 1995; Kenrick et al. 1994; Singh 1993, 1994, 1995; Singh and Luis 1995; Singh and Young 1995; Symons 1995; Wade 2000, 2003). Thus, men seek female partners based on facial and bodily cues and physical qualities that signal these characteristics. Singh and Luis (1995), Symons (1995), and Singh and Randall (2007) report that the most important and most visible physical cue for judging women's attractiveness is the waist-to-hip ratio (WHR). The WHR is related to crucial endocrine states associated with fecundity and successful mothering, and femininity is inferred from it (Singh 1993, 1994, 1995). Singh (1993, 1995) and Björntorp (1987a, b) report that gynoid fat is distributed on the thighs, legs, buttocks, waist, and hips of women. The lumbar curve is also important. Men execute an adaptation that allows them to tell which women have the optimal level of vertebral wedging that allows for a shift of the center of their mass back over their hips during pregnancy. This shifting of the center of mass allows for less: hip torque, lower back pain, spinal injury, and compromised fitness (Whitcome et al. 2007; White and Punjabi 1990). Thus, Lewis et al. (2015) report that men find women whose lumbar curve is closer to the optimal angle of 45.5° most attractive. Additionally, women's waist size is an indicator of their risk for disease, is used to assess their hormonal status, and is correlated with cardiovascular disorders, diabetes, and gallbladder problems (Björntorp 1993; Singh and Young 1995). Therefore, women who appear to have small hips, small waists, medium to small buttocks, and medium legs (Wiggins et al. 1968) are considered more attractive, healthier, more feminine, most fertile, and better potential mothers (Singh 1993, 1994, 1995; Singh and Young 1995; Symons 1995). Women's breasts and the appearance of their stomachs also play a role in attractiveness, health, and fecundity assessments (Singh 1993, 1994, 1995; Singh and Luis 1995; Singh and Young 1995; Symons 1995). Gynoid fat is distributed on the abdomens of women (Björntorp 1987a, b; Singh 1993, 1994, 1995), and women with large breasts are

considered more attractive, more feminine and healthier, and consequently most desirable for long- and short-term relationships (Singh and Young 1995). Physical fitness is also important. Kenrick and Keefe (1992) and Symons (1979) report that good physical fitness is related to fecundity and may also signal phenotypic quality (Symons 1995). Women's sex drives also play a role. The consequences of sexual activity have a greater impact on women (Bailey et al. 1994). Women must bear the offspring that result from sexual activity and experience the body and life changes that are concomitant with that. Thus, men use women's sex drive as a criterion for long- and short-term mate selection. A higher sex drive is associated with both long- and short-term mating (Buss and Schmitt 1993, p. 213, Table 2) preferences. Vocal pitch also plays a role since vocal pitch indexes developmental stability (Hughes et al. 2002). Collins and Missing (2003) report that men find women with higher pitched voices more attractive, and Hughes et al. (2014) report that men find women with hoarser voices more sexually attractive.

Facial Characteristics

Men also seek female partners whose facial characteristics indicate that they are healthy and fecund and have successful mothering potential. So, women with high cheekbones are considered more attractive, feminine, fertile, and healthier (Cunningham 1986; Cunningham et al. 1995; Symons 1995), because women's cheekbone size indexes pathogen resistance (Folstad and Karter 1992; Iwasa et al. 1991; Zuk 1990). Additionally, women with smaller noses are considered more fertile, more attractive, and more feminine (Cunningham 1986; Cunningham et al. 1995; Enlow 1990; Symons 1995; Wade 2000, 2003). The lips are also important. Lip size is also an estrogen-mediated trait (Johnston and Franklin 1993) and an indicator of femininity and attractiveness (Symons 1995). Thus, men rate women with full lips as more attractive (Baudouin and Tiberghien 2004). In addition, since the eyes get smaller with age (Wade 2000,

2003), eye size becomes a heuristic for youth and fertility. So, women with large round eyes are considered more attractive, fertile, and healthier (Cunningham 1986; Cunningham et al. 1995; Symons 1995). Similarly, since the limbal ring, a dark annulus around the iris, gets thinner/lighter due to health problems and/or aging (Peshek et al. 2011), women with a dark and distinct limbal ring around the eye are rated as more attractive than women whose eyes do not have a limbal ring (Peshek et al. 2011).

Conclusion

Both bodily and facial characteristics are important for men's selection of mates. Also, this is not a random process. Men engage in assortative mating where they select mates whose attractiveness matches their respective mate value (Buss and Schmitt 1993; Vandenberg 1972).

Definition

“...competition within the female reproductive tract, between the ejaculates of two or more males for fertilization of female’s eggs” (Parker, 1970).

Introduction

Insects display perhaps some of the most bizarre adaptations to sperm competition in the animal world. Indeed, the first studies of sperm competition, and the consequent definition of the term, were as a result of studies of insects. Geoff Parker’s 1970’s studies of yellow dung flies (*Scathophaga stercoraria*) led him to postulate that:

...copulation with internal fertilization may have arisen by a selective advantage conferred upon males able to eject sperm nearer to the ova than did their fellow males.

Parker was far ahead of the curve. Victorian notions of male and female sexuality had persisted well into the latter half of the twentieth century, and this in turn was reflected in scientific researchers’ understanding of the natural world.

In the *Origin of Species*, Darwin suggested that the cause of differences between male and females in the intensity of selection acting upon them was variation among males in numbers of mates. Yet it was not until 1948 that Angus Bateman was able to experimentally demonstrate in *Drosophila* fruit flies that Darwin was correct (Bateman 1948). However, it was Bateman himself who suggested that when it comes to mating, there is:

...an indiscriminatory eagerness in the males, and a discriminatory passivity in the females.

So, it was considered that whereas males were keen to mate as frequently as possible, and with different females, females themselves preferred quality over quantity.

In the 1980s, following the advent of the molecular age of science, we came to appreciate that females of most species can actually be highly promiscuous, or polyandrous, as a female that remates with different males is termed. For example, DNA fingerprinting in order to ascertain paternity showed that while female birds tend to be socially monogamous, genetically their broods tend to be sired by multiple males. Now, it is known that genetic monogamy is actually extremely rare in the wild. Females of most taxa will mate with multiple males for varied reasons including “trading up” on the quality of the male if their first mate was of poor quality and acquisition of food in species where males provide nuptial gifts (reviewed in Simmons 2001).

Sperm Competition in Insects

Parker (1970) defined sperm competition as:

...competition within the female reproductive tract, between the ejaculates of two or more males for fertilization of female’s eggs.

At its simplest, sperm competition can be viewed as a race or lottery; the faster a male’s sperm travels through the female reproductive tract, or the more sperm he invests in a given ejaculate, the greater the probability that he will “win” fertilization of the female’s eggs.

To date, more is known with regard to sperm competition in the insects than in any other

taxonomic group, due to the ease with which researchers can observe and manipulate them, both in the laboratory and, to an extent, in the wild. There is huge variation in the ways males have evolved to be successful in sperm competition, which is an extremely powerful evolutionary force. Classic early studies showed that in the dark-winged damselfly (*Calopteryx maculata*), the end of the male penis is spoon shaped, allowing the male to scrape any residual sperm from a previous mating from the female reproductive tract, before ejaculating his own. In some butterfly species such as the green-veined white (*Pieris napi*), males transfer a chemical “anti-aphrodisiac” or pheromone to females during mating; this chemical is extremely efficient in deterring subsequent rival males, who will not even attempt to court with the female (Andersson et al. 2000). Finally, male Indian meal moths (*Plodia interpunctella*) are able to determine whether a female has previously mated and adjust accordingly the amount of sperm they ejaculate into the female reproductive tract (reviewed in Wedell et al. 2002). This “strategic sperm allocation” allows males to maximize the chances of their sperm fertilizing the female’s eggs, when sperm competition operates in the manner of a lottery.

Battle of the Sexes

It is not only males that are able to influence the outcome of sperm competition. In 1996 Bill Eberhard published a landmark text, “Female Control: Sexual Selection by Cryptic Female Choice,” which overturned much of sperm competition theory. In it, he suggested that while males were under selection to maximize their success under sperm competition, females were also under to selection to maximize their reproductive success. As noted above, it was well known that females were choosy when deciding to mate with, but Eberhard suggested that they were also choosy after copulation had ended. By manipulating sperm storage and use within her reproductive tract, females could bias paternity toward the sperm of preferred males and thereby influence the outcome of sperm competition.

Concrete experimental evidence that females could bias paternity, thereby exerting what is now called cryptic female choice, was not forthcoming. Indeed, the term cryptic female choice refers to the fact that it occurs within the female reproductive and is therefore difficult – if not impossible – to observe. In 2000 it was showed that in the red flour beetle *Tribolium castaneum*, the intensity of male courtship behavior during mating – in this species the rubbing of the female wing cases with his legs – is directly correlated with male fertilization (Edvardsson and Arnqvist 2000). This was potentially the first experimental study to suggest that females were choosing males on the basis of the intensity of their courtship and biasing utilization of their eggs accordingly.

There are now increasing numbers of studies reporting cryptic female choice in insects. In the cricket *Teleogryllus oceanicus*, females have been shown to assess how closely related a mate is and bias sperm storage toward that of unrelated males (Tune et al. 2013); presumably this is a mechanism of avoiding producing poor quality offspring as a result of inbreeding. In some dragonflies and damselflies, females eject the sperm of non-preferred males prior to oviposition while presumably favoring the utilization of preferred males.

Although covered elsewhere in this volume, it is worth noting here that such interactions between males and females can result in a coevolutionary arms race or “sexual conflict” (Parker 1979). Males of numerous species have evolved tactics which assist them in preventing females remating with other males, or in biasing female utilization of their sperm, to maximize their reproductive success. Conversely, females may wish to remate, if, for example, their first mate is of poor quality, or if they gain food from the male during mating, as noted before. Such conflicting selection pressures can result in coevolutionary cycles whereby males evolve an adaptation to minimize female remating, which results in females evolving a counter-adaption in response to the male adaptation. The classic example is seen in the fruit fly *Drosophila melanogaster*, where males incorporate seminal fluid proteins in their ejaculate which induce female oviposition and reduce

remating, but also decreases female lifespan (c.f. Wigby and Chapman 2004). However, it has been shown that females can evolve a counter-adaptation; when subjected to several generations of increased mating rates and thereby increased levels of sexual conflict, females evolved to reduce the impact of male seminal fluid and their lifespan increased (Wigby and Chapman 2004).

Into the Twenty-First Century

As noted previously, it was the advent of the molecular age and revolutions in technology that allowed researchers to investigate sperm competition in ways that had not previously been possible; indeed, many long-standing paradigms were overturned as a result. As technology has become increasingly cheaper, and increasingly refined, we continue to make breakthroughs in the study of sperm competition in insects. In 2010, for the first time, a team led by Mollie Manier and Scott Pitnick used green- and red-fluorescent proteins to stain sperm in *D. melanogaster* and were thereby able to visualize the movement of competing sperm, *within the female reproductive tract*. The technique led to them discovering that, as explained in the previous section, females were ejecting the sperm non-referred from their reproductive tract after mating.

By essentially artificially inseminating bumblebees (*Bombus terrestris*), Boris Baer and coworkers were able to show that the males produce a mating pug inside the female reproductive tract that physically prevents the female from remating. Additionally, chemical analyses showed that the mating plug contains a fatty acid called linoleic acid, which alters and manipulates the behavior of the queen into not remating. Thus, bumble females are essentially monandrous, mating only once during the course of their lifespan, as they are forced into doing so by the male.

Finally, in 2014, Michal Polak and his group used microscale laser surgery to manipulate the size of a sexually selected ornament of male *Drosophila* flies. These “sex combs” are a microscopic patch of bristles on the front of the forelegs. They found that in addition to being

sexually selected via female preferences, the sex combs also functioned to assist the male in keeping hold of the female during copulation; males who had them removed entirely were unable to copulate.

It is estimated that approximately 10% of species are largely monandrous, with females only mating once during their reproductive lifespan (Taylor et al. 2014). We are still unsure why they are monandrous and therefore not subject to sperm competition, but one thing is clear. In animals that are subject to sperm competition, the little things really matter, and only now do we have the techniques to explore why.

Conclusion

The reproductive lives of insects are remarkable and continue to fascinate the scientists that devote their lives to their study. It has been a long and winding road since Darwin first defined sexual selection in 1869 and Parker first defined sperm competition a century later. Yet we still continue to reveal the marvel that is the inner workings of insect sex, and no doubt, with the arrival of the genomics era and the ever advancing march of technological advancement, there is more to come.

Insight

Zhanna Reznikova

Institute of Systematics and Ecology of Animals of SB RAS, Novosibirsk State University, Novosibirsk, Russia

Synonyms

[Insightful behavior](#); [Rule extraction](#)

Definition

Insight can be attributed to animals' ability for fast integration of behaviors gained from their past experience and effectively applying this

experience for solving a problem as a meaningful whole, in the context of a situation. W. Thorpe (1963) defined “insightful behavior” as “the sudden production of a new adaptive response not arrived at by trial behavior” and “the solution of a problem by the sudden adaptive reorganization of experience”.

Introduction

Wolfgang Köhler (1924) first revealed experimental evidence of insight in chimpanzees basing on ideas of Gestalt psychology. His experiments showed chimpanzees as using planning and foresight, that is, cognitive reasoning to solve a problem. Köhler devised an arrangement in which all of the elements necessary for the solution of the problem were in full view of the animal. One of the most often referred-to examples of problem solving by insight concerns Sultan, a chimpanzee, whom Köhler regarded as the brightest of a number of apes he worked with. Sultan sat in his cage, in which there was also a short stick. Outside the cage there was a longer stick, which was beyond Sultan's reach, and even further away was a reward of fruit. Sultan first tried to reach the fruit with the smallest of the sticks. Not succeeding, he tried a piece of wire that projected from the netting in his cage, but that, too, was in vain. Then he gazed about him and after a long pause suddenly picked up the short stick once more, came to the bars directly opposite to the long stick, dragged it towards him with the auxiliary, seized it, and went with it to the point opposite the objective which he secured. From the moment that his eyes fell upon the long stick, his procedure formed one consecutive whole.

However, in his late publications, Köhler considered a notion of insight rather fuzzy and was frustrated about not understanding the nature of subject's awareness about relations between things that he called insight. In particular, Köhler distinguished two kinds of mistakes related to the problem solving in chimpanzees, that is, “good mistakes” and “bad mistakes”. If the chimpanzee tried to affix a box to a wall in order to reach a

banana from the top of the wall, it is a “good mistake” that can serve as evidence of the animal’s understanding about dimensions; the chimpanzee is simply unaware of box’s properties. But chimpanzees in Köhler’s experiments also demonstrated a lot of “bad mistakes”. For instance, in one setup, chimpanzees could only get bananas by removing a box. Here was something, Köhler expected, that even his awkward chimpanzees could “do at once.” And yet, to his astonishment, the chimpanzees had difficulties in solving such problems; they often drew into the situation the strangest and most distant tools and adopted the most peculiar methods, rather than removing a simple obstacle which could be displaced with perfect ease. Many years later, Elisabetta Visalberghi (2002), referring to her observations on adult male capuchin pounding an unshelled peanut with a boiled potato, raised a question why capuchins were doing something smart in a silly way, or something silly in a smart way.

Insightful behavior in Human- and Non-Human Animals

The concept of insight introduced by Köhler has been immediately appreciated in human studies. Psychologists identified this phenomenon as “aha!” (“Eureka”!) solutions referring to the well known Archimedes legend. Maier (1931) suggested problems for studying human insight similar to those that were solved by apes, for example, the two-string problem: two strings hanging at two arm-span widths apart need to be tied together, and the items in the room may help. Many human studies are based on human-specific skills such as solutions of Checkerboard problems (Kaplan and Simon 1990) and verbal problems (Jung-Beeman et al. 2004). At the same time, many modern comparative studies of insightful behavior are performed simultaneously on animals and human infants.

In modern cognitive ethology, insight is considered a part of rule extraction, that is, of the learning class which includes casual reasoning

and concept formation. Insightful behavior is based on the animals’ capacities for formation of “what-leads-to what” expectancies which, in turn, are closely connected with their exploratory activity (for details see: Reznikova 2007).

Currently experimental paradigms for studying insight in animals are often based on “folk physics” of animals, that is, their common-sense understanding of how the world works, as well as why it works in the way it does. For example, many experiments testing birds’ abilities to use a physical object to obtain food that is out of reach have involved the string-pulling task known since ancient times. In experiments of Heinrich (1995) with common ravens, it is required that the bird repeats the following sequence several times: reaching down from the perch, grasping the string with the beak, pulling the string up, placing the pulled-up loop of string on the perch, then pressing a foot down on the loop and letting go with the beak, so that the bird can reach down to pull up another loop. Keas (New Zealand parrots) completed the first trial within a few seconds, by showing only goal-directed behavior, thus executing the solution in a manner that could not be improved upon in further trials (Werdenich and Huber 2006). Hooded crows could successfully solve tasks in which the strings did not cross each other but were arranged in such a way that the bait was opposite the end of an “empty” string. They also solved a task in which the bait was attached to each of two strings but one string was broken, preventing it from pulling the bait (Bagotskaya et al. 2012). All these results demonstrate birds of several species as understanding of means–end relationships, i.e., the apprehension of the cause–effect relation between strings, food, and certain body parts.

Another problem also known from ancient times which is involved in insight studies comes from the Aesop’s fable in which a thirsty crow threw stones into a pitcher to raise and drink the otherwise inaccessible water. In the experiment of Bird and Emery (2009), the rooks solved a similar problem: they dropped stones into a tube of water in order to bring a floating worm within reach. Orangutans

(Mendes et al. 2007) and chimpanzees (Hanus et al. 2011) also have insightfully solved an analogous version of the problem. Apes were presented with a tube quarter-filled with water. Floating on the surface of the water was a peanut. To solve the problem, the apes needed to collect water from a drinking container in their mouths and spit it into the tube in order to raise the water level and gain the peanut. After trying to reach the peanut with their fingers or mouths, animals spat water into the tube in order to raise the level and so gain the reward on the first trial. Chimpanzees and orangutans performed better than 4-year-old children and worse than 6- and 8-year-olds in the same experiments.

Conclusion

Insight can be considered a part of the mental process that relates to understanding relationships. In problem solving, the experience need not be directly associated with the problem at hand. Sometimes, when presented with a new problem, an animal will solve the problem on the first attempt using the previous experience in dealing with the component parts of the problem, although they were never met together in just such a way before. There is much work to be done to extend our understanding of whether at least some species can take into account imperceptible physical forces or they are only capable of reasoning about perceptible things. To clear up this problem to a lesser or greater extent, developmental studies are needed that will allow a distinction to be made between inherited and acquired behavior.

Insist on No More than Equity

Natalia Dutra

[Distributive justice](#); [Equity](#); [Reciprocity](#)

Definition

“Insist on no more than equity” is one important aspect of reciprocity and a way of solving social dilemmas cooperatively.

Introduction

Equity can be defined as the distribution of resources between people according to their contribution or necessity. Insisting on no more than equity is a characteristic of successful cooperative strategies in social dilemmas, that is, situations in which individuals interests are in conflict and they may be tempted to adopt selfish choices. Axelrod (1984) states that “a strategy based on reciprocity can allow the other player to get the reward for mutual cooperation, which is the same payoff it gets for itself when both strategies are doing their best” (p. 137). In other words, reciprocity means that individuals will receive back from others the equivalent of what they invested, and equity in reciprocity means that everyone in an interaction will eventually get their fair share. Thus, equity seems to be a condition for reciprocity.

Whereas equity means treating others according to their characteristics and actions, equality means treating other in the same way. For instance, someone sharing food equitably will give more food to those who are hungrier or worked harder, while someone sharing food equally will share the same amount to everyone regardless of effort or need. Equity concerns and

reciprocity in humans underlie our sense of fairness and social institutions, most prominently our justice systems. This entry explores how equity and fairness manifest in humans, from an evolutionary perspective.

The Relationship Between Reciprocity and Equity

Evolutionary models of altruism are in essence attempts to explain the occurrence of altruism in what otherwise are considered selfish individuals, from a genetic standpoint. The reason for this is that evolution tends to favor the survival and reproductive success of lower levels of organization. Thus, any strategy that favors the reproduction of genes will tend to spread in a group, even if at the expenses of organisms and groups. This is why group selection is considered rare in nature, because selection at an individual level will tend to be more powerful than at the group level. This reasoning can be applied to the evolution of cooperation from a previous non-cooperative state; if selfish individuals benefit from cooperation, but have less costs or more benefits than cooperators in a group, they will tend to outperform cooperators in the long run (that is, leave more descendants in the next generations).

Axelrod (1984) introduced “insist on no more than equity” as one of the strategies to promote reciprocal cooperation in the long run, based on computer simulations of multiple rounds of an economic game called the prisoner’s dilemma. In these simulations, called computer tournaments, several strategies submitted by game theorists competed in repeated interactions, until one or more of them became victorious. The prisoner’s dilemma is illustrated by the example of two accomplices who have been arrested by the police and are kept in separate rooms. They cannot communicate with each other and have to make one of two decisions: either “cheat” and denounce the other prisoner, thus getting a shorter sentence; or “cooperate” and keep quiet, therefore receiving a longer sentence. However, the length of the sentences are dependent on both prisoners’ decisions, in such way that cheating the partner is

always the best individual choice in the short term. In this scenario, the strategy that was classically victorious in the computer tournaments used a simple heuristic: always cooperate first, repeat the partner previous move in subsequent interactions. Due to its simple reciprocal rule, the strategy was called Tit-For-Tat, and it is an equitable strategy because in the long run partners who adopt this strategy will end up with the same amount of points.

Reciprocity in humans and other species has probably evolved as a social strategy to maintain mutual cooperative relationships (Baumard et al. 2013; Trivers 1971). Reciprocity can be either direct, that is, when an individual is reciprocated by the same individual they have helped before; or indirect, that is, when an individual is helped by someone else than those they have helped before (Alexander 1985). It can also be either immediate or delayed. When immediate, it does not pose much problem for those involved, given that cheating is difficult. Delayed reciprocity, in which an individual receives a return for his helping actions some time in the future, leaves room for exploitation. Humans are among the rare examples of delayed direct reciprocity in the animal kingdom (another famous example are the vampire bats, Carter and Wilkinson 2013; Trivers 1971).

For reciprocal interactions to take place and promote successful cooperation, individuals must be able to judge other actions based on past behavior, contribution to the interaction, and chances of having the helping act reciprocated within their lifetime (Stevens et al. 2005). Or, in absence of these skills, individuals should be able to detect environmental cues such as territoriality or similarity, which make repeated interactions between the same partners possible without sophisticated mechanisms for recognition (Axelrod and Hamilton 1981; Riolo et al. 2001). In addition, social groups must be constituted in ways that allow for non-reciprocators (also called cheaters or free-riders) to be excluded or punished. Obligatory reciprocal interactions, such as collaborative foraging, could have led to the evolution of unique cooperative skills regarding the equitable sharing of resources, and the

subsequent creation of social norms and institutions (Tomasello et al. 2012).

Equity in Human Societies

Morality can be defined as cooperative behavior (Curry 2016). Several authors proposed that the mechanisms of direct and indirect reciprocity underlie human moral systems. If an individual is not helpful with or good towards others, they might lose the others support when they need it. The same logic is applied in interactions with friends and romantic partners (Buss 2000), and it is even more relevant in the context of small-scale societies, which rely on mutual interdependence to survive in harsher environments (Cronk et al. 2019).

The Golden Rule can be summarized by: “do to others as you would have them do to you,” and it appears in different forms across many religions and cultures (Blackburn 2001; Wattles 1996). It is considered, in its purest form, as a call for generosity towards others. However, the Golden Rule as it is practiced within societies takes up meaning more closely associated to the notions of reciprocity and equity. Thus, the Golden Rule is an example of the application of the principle of insisting on no more than equity across societies and an indication of the universality of this trait in humans.

The way societies organize themselves around their moral systems, however, can vary across social and economic conditions. One popular way of measuring reciprocity, equity, and fairness across societies is the use of economic games. Henrich et al. (2005) ran experiments using three of such games (the ultimatum game, the dictator game, and the public goods game) in 15 small-scale societies with varied levels of social and economic conditions. They found significant differences across societies in the amount donated in these games, more specifically with regards to the level of market integration and local importance attributed to cooperation in each society.

Consider, for example, the Aché and the Hadza, both considered small-scale foragers. Both societies are often used as models to test

hypotheses about the mode of living of early humans (Apicella et al. 2012; Marlowe 2005) and are widely viewed as egalitarian societies. However, they differ with regards to their sharing behavior. The Aché spontaneously share more meat with other members of the community, while the Hadza reluctantly share meat with others, and mostly due to social pressure. Thus, when asked to play the ultimatum game (in which a participant receives a certain amount and makes an anonymous offer to another participant, who can then accept it or decline it; if they decline it, both participants get nothing), the Aché had had higher offers (40% or more of the amount) and lower rejection rates than the Hadza, thus showing greater concern with equity in their decisions in the game.

Equity Across Development

There is mounting evidence of universally evolved sense of fairness in humans, even though with differences in developmental trajectories influenced by cultural and demographic factors. In Western countries, earlier evidence from classical psychological studies indicated that children only developed equity concerns by the age of six or seven (Damon 1977). Piaget (1932), based on observations of Swedish children's games, proposed an even later stage: "between 7 and 10 sheer equality in all its brutality still outweighs equity" (p. 216). More recent evidence, however, shows that preschool children are able to take effort and merit into account when distributing resources (Baumard et al. 2012).

However, this apparent contradiction might explained by the developmental trajectory of prosocial behavior, as revealed by a study across several different cultures (House et al. 2013), which shows that young children in these cultures show a similar pattern of behavior around the age of three, which then declines until the age of five or six, and increases again but in diverse ways across different cultures. More importantly, these differences were only found for costly prosocial behavior, which indicates the role of culture in influencing patterns of behavior that are socially

enforced, even when individual interests are in conflict with those of the group.

Western European 3-year-olds are able to judge others' contribution in a joint task and share accordingly, thus taking merit into account (Baumard et al. 2012; Paulus 2015). Moreover, children seem capable of distinguishing between different characteristics while sharing goods. Thus, they take merit, but not gender, when making sharing decisions, thus sharing equally among gender, but not among those who contribute more and less to the activity (Rizzo et al. 2018). Children in the United States increasingly take effort into account, even more than productivity (Noh et al. 2019). Children from more individualist cultures such as the United States, however, may tend to share more with less wealthy individuals, even if they make less effort in a task (Paulus 2015); whereas children from more collectivist societies such as China may tend to focus on the effort and ignore wealth inequality as a factor in their sharing decisions (Chai and He 2017). Thus, though humans show a universal propensity to develop equity concerns and a sense of fairness, both traits may vary across development according to social and cultural factors.

Conclusion

Insisting on no more than equity is a successful strategy in the context of reciprocal cooperation. It is likely that equity concerns in humans have given rise to our sense of fairness and, in interaction with cumulative cultural evolution, led to the evolution of our social institutions (Boyd and Richerson 2009). Equity is a component of fairness, and it protects individuals from exploitative relationships, while also promoting more equitable relationships between those with different amount of resources.

In human societies, these principles are present in many institutions, even if it did not prevent the rise of social inequality. This is probably due to a combination of reciprocal and nepotist systems, in which individuals will seek to profit the maximum for themselves and their families and closest relatives and friends, while also seeking from the

same support when they need. In an individual level, humans and other animals will seek reciprocity from their allies and close kin, but in a group level, social institutions will be often in conflict with individual interests to assure cooperation among its members. A relevant aspect of this is that, once social groups are in competition with each other, those societies who foster more cooperation among its members will tend to out-compete those who do not. In this context, equity tends to be a rule among the members of the same group (Romano et al. 2017) but not necessarily with regards to other individuals.

Definition

How to design instructional procedures.

Introduction

Governing principles of instructional design can be derived from our knowledge of human cognition. In turn, the characteristics of human cognition are intricately bound in the structures and processes of evolutionary psychology. Cognitive load theory (Sweller et al. 2011) uses human cognitive architecture and evolutionary psychology to devise novel instructional procedures. Only some categories of knowledge can provide substantive subject matter for instruction with evolutionary psychology determining which subject matter can be meaningfully taught. Furthermore, the processing characteristics associated with teachable information closely mimic the information processing characteristics of biological evolution allowing us to use the well-known processes that guide biological evolution as a template to assist in understanding aspects of human cognition relevant to instructional design. Categories of knowledge that are relevant to instruction will be discussed first, followed by the cognitive architecture that governs the manner in which instructionally relevant information is processed, and ending with cognitive load theory's use of this base to generate instructional procedures.

Categories of Knowledge

Most knowledge categorization schemes do not have instructional implications. One scheme, introduced by David Geary, is directly relevant to instructional design (Geary 2008; Geary and Berch 2016; Sweller 2016). Geary divided knowledge into biologically (or evolutionary) primary and secondary knowledge. All knowledge can be placed into one or other or a combination of these two categories depending on the evolutionary status of the relevant knowledge.

We have specifically evolved to acquire biologically primary knowledge. Examples are

learning to listen and speak a native language, learning to recognize faces, generalizing learned knowledge, regulating our thought processes, or using general problem-solving strategies. Biologically primary knowledge has several important characteristics. It tends to be acquired relatively easily and automatically without conscious thought. As can be seen from the above examples, it is frequently associated with generic-cognitive skills (Tricot and Sweller 2014) that we have specifically evolved to acquire because of their importance. Biologically primary skills are usually acquired at different evolutionary epochs, and as a consequence, they tend to be unrelated and modular. From an instructional perspective, while they can be improved with practice, they cannot be taught because they are naturally acquired without instruction.

In contrast to biologically primary skills, secondary skills are much more closely related to instructional issues. These are skills that we can acquire but that we have not specifically evolved to acquire. They are important for cultural reasons. Examples come from virtually every topic taught in education and training institutions. Such institutions were devised precisely in order to teach biologically secondary skills that were deemed to be culturally important but which we had not evolved to acquire. While most such skills rely on biologically primary knowledge for their acquisition (Paas and Sweller 2012), the manner in which they are acquired is very different to the acquisition of primary knowledge. Secondary skills can be difficult to acquire despite encapsulating far less information than biologically primary skills. They require conscious, deliberate effort rather than being acquired automatically. Most commonly they are domain-specific rather than generic-cognitive in nature. As an example, while we may have evolved to automatically acquired a general problem-solving strategy to attempt to solve any problem that we encounter, we have not evolved to automatically acquire the means to solve a problem such as $a + b = c$, solve for a . We must deliberately and consciously learn the relevant procedures, and we are assisted in that task by explicit tuition (Kirschner et al. 2006; Sweller et al. 2007).

Instructional design is largely concerned with the best procedures for assisting learners to acquire biologically secondary knowledge. Those procedures depend on aspects of human cognitive architecture associated with the acquisition of secondary knowledge. That architecture allows humans to process information analogously to the manner in which evolution by natural selection processes information.

Human Cognitive Architecture

Five basic principles may be used to describe how the human cognitive system processes biologically secondary information. Those five principles also can be used to indicate how evolution by natural selection processes information. Both human cognition and evolution by natural selection provide examples of analogous, natural information processing systems (Sweller and Sweller 2006).

The Information Store Principle

In order to function in a natural environment, a natural information processing system relies on a very large store of information. In the case of evolution by natural selection, a genome provides that store. Long-term memory has a similar function in human cognition. If anything is learned, if a new skill is acquired, it has been stored in long-term memory. Without such storage, nothing is learned. It follows that the major goal of instruction is to assist learners to store biologically secondary information in long-term memory. Our ability to store information in long-term memory is biologically primary. Cognitive load theory and its instructional prescriptions are based on the assumption that a major purpose of instruction is to store large amounts of information in long-term memory.

The Borrowing and Reorganizing Principle

Given the enormous size of natural information stores, how such information is acquired becomes an immediate question. In the case of evolution by natural selection, the process is well-known. Genomes are borrowed from ancestors during

sexual or asexual reproduction. In the case of sexual reproduction, two immediate ancestors are required allowing the information to be reorganized. In the case of human cognition, the acquisition and storage of large amounts of information in long-term memory also require the information to be borrowed from others before being reorganized. We imitate other people, listen to what they say, and read what they write in order to obtain information to be stored in long-term memory. Information is reorganized during storage when it is combined with previously stored information. Our ability to obtain biologically secondary information from other people is biologically primary. Given the importance of obtaining information from other people, instructional design needs to be organized in a manner that facilitates information transfer. Cognitive load theory was designed for this function.

The Randomness as Genesis Principle

While obtaining complex information from elsewhere using the borrowing and reorganizing principle is efficient, it is not always possible. The information may not be readily available to be borrowed or may not as yet even been assembled in a form that allows borrowing. Information that is borrowed must at some point have been initially assembled or created. The manner in which evolution by natural selection creates novel information is well-specified. Random mutation is the core of the process with all variations between all life forms assumed to be ultimately sourced to mutation. It is a random generation and test process with successful mutations retained for subsequent generations and unsuccessful mutations resulting in fewer or no offspring.

The randomness as genesis principle plays the same role in human cognition as in evolution by natural selection. When required information cannot be obtained from others via the borrowing and reorganizing principle, it may be created during problem-solving. If we do not have access to information because we do not have access to the required people or to their writing or if the required information has never been assembled by anyone else, we can attempt to assemble it ourselves by conducting research. Just as all

novel genetic variations can be sourced to random mutations, all novel ideas ultimately can be sourced to a random generation and test process during problem-solving.

While we sometimes have to engage in problem-solving to obtain information, it is neither an effective nor an efficient mode of learning. Obtaining information from others via the borrowing and reorganizing principle is far more effective and efficient, a factor that needs to be considered when designing instruction.

The Narrow Limits of Change Principle

The randomness as genesis principle has structural implications. The number of possible random combinations of elements increases exponentially with increases in the number of elements that must be processed. Both evolution by natural selection and human cognition have structures and functions designed to limit the number of novel elements of information that can be processed at any given time.

In the case of evolution, the epigenetic system is used to limit the number and the genome location of mutations. For example, if environmental pressures require diversity, the number of mutations can increase by a factor of many thousands. Nevertheless, in general, the number of mutations tends to be limited in order to ensure that the organizational integrity of the genome is not destroyed. As a consequence, the randomness as genesis principle is constrained by the narrow limits of change principle.

Working memory plays a similar role in human cognition as the epigenetic system plays in evolutionary biology. When dealing with novel information, working memory constrains the number of elements of novel information that can be processed and the duration that they can be held. The contents of long-term memory are protected by these limitations.

This principle is central to the instructional design prescriptions of cognitive load theory. When instructing learners, it is important to organize the instruction to minimize the working memory load imposed. Ignoring the working memory limitations of learners invites instructional failure. Cognitive load theory has generated

a large number of cognitive load effects indicating instructional procedures designed to lessen extraneous cognitive load and so facilitate learning which consists of the transfer of information to long-term memory.

The Environmental Organizing and Linking Principle

The narrow limits of change principle apply only to novel, unorganized information from the environment. It does not apply to the organized information stored in the information store. With respect to evolution by natural selection, the epigenetic system permits large amounts of stored, genomic information to be used to govern activity. Based on environmental signals, the epigenetic system can activate some genes and suppress others to determine activity appropriate to that environment. There are no known limits to the amount of stored information that can be used. In that way, a liver cell and a kidney cell with identical DNA have vastly different phenotypes resulting in vastly different structures and functions.

Similarly, the capacity and duration limits of working memory relevant to the narrow limits of change principle disappear when dealing with organized information from long-term memory. Environmental signals are used to activate relevant information stored in long-term memory while ignoring irrelevant information. Relevant information then can be transferred to working memory to govern environmentally appropriate action, with no known limits to the amount of information transferred. It is in this manner, that education transforms us. We can successfully act in a manner that would be impossible without acquired, biologically secondary information.

Conclusions: Cognitive Load Theory and Instructional Design

This cognitive architecture provides a base for the instructional procedures generated by cognitive load theory. The procedures apply to biologically secondary, domain-specific information that we have not specifically evolved to acquire. That information provides the instructional content of

education and training. It needs to be explicitly presented to learners in a manner that reduces working memory load. Once learned, it is stored in long-term memory to be transferred to working memory in order to govern behavior that is appropriate for a given environment.

There are many instructional procedures generated by cognitive load theory (Sweller et al. 2011) with new procedures under constant development (Chen et al. *in press*). Each procedure is designed to facilitate the transfer of information to long-term memory by reducing unnecessary working memory load. All recommended procedures are tested for relative effectiveness using multiple, randomized, controlled trials. The considerable variety of cognitive load effects generated by the theory all have in common the assumptions that the domain-specific, biologically secondary information that forms the subject matter of instruction must be stored in long-term memory for later use and that storage is best effected by explicit presentation of the information in a manner that reduces working memory load during acquisition. These assumptions flow directly from the evolutionary psychology base and consequent cognitive architecture that undergirds the theory.

Definition

An influential definition of human intelligence is “a very general mental capability that, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience. It is not merely book learning, a narrow academic skill, or test-taking smarts. Rather, it reflects a broader and deeper capability for comprehending our surroundings – ‘catching on,’ ‘making sense’ of things, or ‘figuring out’ what to do” (Gottfredson 1997a, p. 13).

Introduction

One of the striking facts about our universe is that it contains intelligence. Somehow, planet Earth went from a barren, scorching planet into a flowering display of life. Eventually, *Homo sapiens* (“wise man”) was the first species on Earth, and possibly in the universe, that started to talk, generate rich cultures, send conspecifics and electronics to space, and invent abstract algebra and calculus.

Why did intelligence evolve in the first place? This question seems unreasonable at first sight because it is hard to imagine anything more useful than intelligence. Nevertheless, intelligence comes packed with disadvantages. A key hint about the cost of intelligence is the fact that it is relatively rare in nature. In fact, many organisms do just fine without a brain at all. Moreover, intelligence has evolved independently only a few times (convergent evolution) in some mammals, cephalopods (e.g., octopi), and birds (Emery and Clayton 2004). Further, although just 2% of the total body weight of humans, the brain consumes 20% of the calories consumed (Aiello and Wheeler 1995), and Mother Nature does not spend calories unnecessarily. Nevertheless, the brain expanded threefold in just under 2 million years, suggesting that selective pressures forcefully aligned to produce intelligence in the *Homo* line.

This entry will briefly discuss (1) the science and psychometrics of human intelligence, (2) how intelligence works from an information

processing point of view, and finally (3) models and evidence on why human intelligence evolved.

The Psychometrics of Intelligence

Key parts of human intelligence are the abilities to learn, reason, and solve problems (Plomin and von Stumm 2018). These abilities to learn and reason also differ dramatically between people and can be reliably measured with tests such as the Wechsler intelligence scale (Wechsler 2008) and Ravens progressive matrices (Raven and Court 1998). The latter test consists of a series of multiple choice questions based on matrices. The subject is shown a 3×3 matrix containing symbols where the last one is omitted, the subject then chooses a symbol from multiple possible responses based on identification of the underlying rule generating the matrix. In modern measurements of intelligence, a person's intelligence is estimated by taking the subject's raw score on several mental abilities and comparing it to the average performance of a representative group in the subject's age range. This is called *deviation intelligence quotient* (IQ) (Urbina 2011). The normalized IQ distribution has an average of 100 and a standard deviation of 15. Intelligence tests are important clinically, because they are used to diagnose intellectual disability in children and adults (a diagnostic criteria being IQ below 70) and to assess milder cognitive deficits caused by brain injury and neurodegenerative disease.

A classic empirical finding, first made by Spearman (1904), is that test scores on several specific and different intellectual abilities covary and hence form the statistical abstraction called general intelligence (*g*). In other words, people who score well on one particular cognitive ability tend to score well on others. Based on these findings, general intelligence is understood psychometrically as a latent trait, meaning that it is not measured directly, but inferred from several measured cognitive abilities such as verbal and spatial abilities. However, every cognitive domain also has some degree of specificity. For instance, it is possible for an individual to score above average in logical ability but below average in verbal

ability. In fact, a large controversy in the history of intelligence theory and research concerns how to understand both the general and the specific aspect of intelligence. Many theoreticians agree that *g* is important for all mental abilities (Jensen 1998), while others claim that humans have multiple and separate intelligences, such as interpersonal and musical ability (e.g., Gardner 2011). However, the latter theory seems to be a synthesis of general and specific intelligence, as well as noncognitive abilities and personality traits (Visser et al. 2006).

Today intelligence has emerged as a generalist concept that influences many real-life outcomes. Most obviously, it predicts educational attainment (Jensen 1998), but intelligence is also a strong predictor in a wide range of nonacademic areas. In fact, intelligence predicts general health and longevity (Hart et al. 2003), and it is the single best predictor of success in job training and performance, with predictive power increasing with job complexity (Schmidt and Hunter 2004). Overall, intelligence is the best single predictor for both favorable socioeconomic outcomes, such as good education, occupation, and income, and negatively for unfavorable outcomes such as adult poverty, incarceration, and chronic welfare use (Gottfredson 1997b; Gottfredson and Deary 2004).

How Intelligence Works

How can a vast collection of unintelligent neurons produce intelligent behavior? Intelligence cannot, of course, arise out of lumps of brain matter alone. Instead, intelligence is produced by the *computations* going on within the neural tissue. That is, human minds can do intelligent things because nervous systems represent, process, and transform information (Clark 2014). One key property of a computational system is the ability to change its operation based on information (Cosmides and Tooby 2002). Hence, computational processes can be seen as independent of the physical machinery in which it occurs. For example, the plastic cover on a thermostat is not a computational system, but the thermocouple that responds to a particular room temperature and turns on the

switch that activates the heat-generating parts of a furnace is a computational system. Similarly, the visual system in the human brain that detects the presence of a predator and activates muscles that either makes a person run away if the predator has seen it, or freeze if it has not, is a computational system (Cosmides and Tooby 2002).

How does the computing in neural circuitry actually work? One approach in cognitive science, called *connectionism*, uses the insights gained from artificial neural networks to shed light on how intelligence can be produced (Elman et al. 1998). The design of computer-programmed artificial neural nets works by many interconnected nodes that are modified by a learning rule that, over time, strengthen particular connections to produce the desired outcome (Striedter 2005). Hence, in the connectionist perspective, the knowledge base residing within neural structures are composed of sets of simple processors linked by a daunting mass of wiring and connections (Clark 2014).

However, another important approach, called the *physical symbol system*, is that computation works by more abstract symbol manipulation (Newell and Simon 1976). This is akin to how a digital computer works, namely, by manipulating symbols (the famous zeros and ones), while the CPU do operations on them.

Although you can get far with simple connectionist models for modeling intelligent human behavior, it also runs into problems. Generally, they can fail to capture the flexibility and power of everyday reasoning. For example, when representing complex relations between bits of knowledge or generalizing abstract relationships, hence, brain circuitry that produces intelligent behavior might best be construed as a complex combination of both connectionism and symbol manipulation (Marcus 2003).

Modularity

Within classical evolutionary psychology, it is often thought that the mind consists of several special-purpose modules that solve particular problems that were relevant in past evolutionary environments (Barrett and Kurzban 2006). This has been dubbed the *massive modularity*

hypothesis. In this view, the mind contains a vast array of tools that solve particular problems, rather than content-independent, abstract reasoning devices.

There are good reasons to believe that complex brains are modular. For example, within robotics research, installation of special-purpose tricks is often the only effective ways of generating adaptive behavior in real time (Clark 2014). It is likely, therefore, that the mind consists of many specialized subsystems running in parallel, rather than a few general problem solvers.

However, how can the modularity view explain intelligence, that clearly involves usage of content-independent reasoning to solve novel problems? This is in itself a difficult problem because it is hard to conceive how the alternative, namely, content-free and general-purpose minds, could generate intelligence. This would be akin to a smart phone solving complex tasks (reading maps, taking pictures, and so on) without any special-purpose apps installed on it.

A useful distinction is to consider two types of intelligence: (1) dedicated intelligence and (2) improvisational intelligence. Dedicated intelligence is the degree to which a neural program, or module, is able to efficiently solve a particular set of computational problems. Improvisational intelligence, on the other hand, reflects the ability to exploit transient or novel conditions to achieve adaptive outcomes (Cosmides and Tooby 2002).

How is improvisational intelligence achieved? An answer might be that human *g* relates more closely to evolution of *interactions* between evolutionarily recent neural circuitry, rather than the evolution of evermore specialized modules alone (Jung and Haier 2007). Although brain networks are highly modular, there is evidence that individual differences in human general intelligence is not associated with the number or size of modules but in the connectivity between and within modules, particularly in frontal and parietal brain regions (Hilger et al. 2017). Nevertheless, concrete knowledge about how this connectivity produces intelligence might depend more on progress in artificial neural nets and general artificial intelligence than from the direct study of the messy biochemical reality of neuroscience.

The Evolution of Intelligence

Around 2 million years ago, *Homo erectus* (also known as *Homo ergaster*) appeared in Africa. This was the ancestor of ancient *Homo sapiens* and *Homo neanderthalensis* (Klein 2000). The size of the brain of *Homo erectus* was twice as large as any living nonhuman apes and had roughly 75% the brain capacity of modern humans (Gabora and Russon 2011; Ruff et al. 1997). *Homo erectus* has left evidence of human-like characteristics; they made stone axes, engaged in long-distance hunting, and had the ability to adjust lifestyle based on season (Gabora and Russon 2011).

Two major brain expansions occurred during the evolution of the homo line. The first was around 2 million years ago (Klein 2008), and the second one was between 600,000 and 150,000 years ago, marking the appearance of anatomically modern *Homo sapiens* (Gabora and Russon 2011; Ruff et al. 1997).

The fully grown human brain weighs around 1500 g, which is more than three times heavier than for every other living primate (Striedter 2005). Nonetheless, brain weight correlates with the overall size of an organism, so information about brain weight alone is not a useful proxy for the relative intelligence of a species. Therefore, it is more informative to look at ratios between brain and body weight. However, this ratio can be misleading too because smaller animals generally have higher brain to body ratio than larger ones (pocket mice have a higher brain-body ratio than humans do, for instance). Given this nonlinearity, the most useful measure of relative interspecies brain size is the encephalization quotient (EQ). EQ is the ratio between predicted and actual brain mass of a particular species given information from several reference species (Striedter 2005). Examples of EQ scores for various species are the African elephants with an EQ of 1.3, the mouse with 0.5, chimpanzees 2.2–2.5, dolphins 5.3, and humans, with the highest score of all species, 7.4 (Roth and Dicke 2005).

The cradle of humans was in equatorial Africa (Klein 2000), and it was here that humans first

occupied and exploited what has been dubbed the *cognitive niche* (DeVore and Tooby 1987). A niche often refers to what an animal does in its local ecology: It can be said to describe the profession, biologically speaking, of an organism (Odum 1959). Rather than exploiting resources by purely physical and chemical means (e.g., running faster, stronger toxins, and so on), humans are able to extract resources from the environment by using cognitive models of causal relationships in the world. This allows humans to invent tools and weapons, extract poison and drugs from other living organisms, and engage in coordinated action with other people; all embedded in culture (Pinker 2010).

The Cost of Evolving Intelligence

As mentioned in the introduction, evolving large amounts of brain tissue is calorically expensive. Furthermore, greater intelligence requires larger brains and therefore a larger cranium in which to contain it, and giving birth to increasingly big-brained children was risky due to the close correspondence in size between the maternal pelvis and the neonatal cranium (Rosenberg and Trevathan 2002). This evolutionary problem leads to humans being born at an earlier stage in development, giving the brain time to grow postnatally instead. This gives rise, in part, to the particularly long childhoods among humans, years that are spent in apprenticeship within the local culture, using ever-increasing intelligence to acquire skills for survival and social know-how (Bjorklund and Hernandez Blasi 2016; Pinker 2010).

All the extreme traits that are characteristic of humans such as language, sociality, long childhoods, and long investments from fathers and grandparents, and usage of different food sources, have likely all contributed to the development of *Homo* intelligence (Street et al. 2017). Language, for instance, allows for effective communication of know-how, which in turn allows for more sophisticated problem-solving and social cooperation.

However, evolution of the human brain and human cognitive ability was probably not just simply due to cooperative hunting, meat eating, or tool usage because the fossil records show that

these behaviors preceded the main brain expansions in humans (Klein 2000).

Another set of unusual human traits that might have coevolved with increased intelligence are the unusual sexual characteristics of humans. The human species have a reduced sexual dimorphism: Men are still larger than females but less so compared to other apes, suggesting selection for monogamy, biparental care, and general mating cooperation. This might be a crucial step given the extended childhood of humans. Babies require very costly parental investment in order to survive to reproductive age themselves, and human males do provide care and protection toward their offspring to a greater degree than other male apes (Flinn et al. 2005; Gabora and Russon 2011; Pinker 2010).

What selective pressures drove the brain expansions, despite all the costs, within the homo line and in anatomically modern *Homo sapiens*?

Models of the Evolution of Human Intelligence

There are several models on why intelligence evolved in humans. The following section will briefly discuss two important models on how it got started: ecological dominance and the social brain model. Then, lastly, we discuss the possible role for sexual selection in explaining the extraordinary intelligence of humans.

Ecological Dominance

The ecological dominance model on the evolution of human intelligence stresses that the hominin line was able to increasingly master the hostile forces of nature, such as procuring food, keeping warm, survive, and finding mates (e.g., Flinn et al. 2005). Several parts of the human mind are useful for ecological dominance. For example, more than any other animal, humans have “scenario-building” abilities, including foresight, planning, and “autonoetic” functions – the ability to do mental time travel. All of these functions are related to the most recently evolved parts of the brain, namely, the prefrontal cortex.

In fact, humans are the only species that can mold its environment and even entirely remove other aspects of nature, including other species,

from its environment (Alexander 1990), suggesting that intelligence evolved at least partly as a means to overcome classic ecological challenges.

Ecological dominance is likely to be an important factor in the evolution of human intelligence. However, a problem with the model is that it does not explain why humans evolved the *exceptional* cognitive abilities that they have. Many other species hunt, live on savanna habitats, have extended lifetimes, and have generally gone through similar selection pressures in their ecology without ever coming close to evolving the relative brain size and intelligence of *Homo sapiens* (Flinn et al. 2005).

Social Brain

The social brain model postulates that human intelligence evolved due to the social chess humans have played throughout evolution – namely, in dealing with *other* intelligent hominin creatures. After humans dominated and mastered their ecology, these social selective pressures might have been even more consequential. Predicting future moves and countermoves of competitors and cooperators is complex, especially when amplified by deception and shifting coalitions. Climbing social hierarchies is crucial for mating success, a complicated game that strongly rewards intellect (Dunbar 1998; Flinn et al. 2005). Hence, a crucial part of the social brain model is that people who are more sophisticated socially can manipulate other individuals to gain control over resources and other people's behavior. Moreover, humans have also evolved the capacity for prosociality and cooperation. That is, individuals display moral and altruistic sophistication toward both kin and nonkin, making them more attractive as social partners (Nesse 2007).

There is a correlation in group size of a species and brain size (Dunbar 1998). Many highly developed mental abilities in humans are also directly related to social functioning. For example, theory of mind (ToM), the ability to ascribe and understand the intentions and mental states of others, is well developed in humans and have severe negative consequences (autism) when dysfunctioning (Baron-Cohen 1997; Dennett 1989; Nesse 2007).

Sexual Selection: Is Human Intelligence a Fitness Indicator?

In sexual courtship many animals advertise their genetic quality with their bodies and minds (Miller 2000, 2011). The male bowerbird, for example, is famous for its exquisite architectural abilities (Day et al. 2005). Male bowerbirds arrange their bowers out of twigs and ornament them with petals, glossy beetles, and even colorful human-made objects such as pens and dollar bills. Arguably, the male applies its skills as an architect, carpenter, and interior designer sending potential mates a signal saying “I am able to build this particularly complicated bower because my genome contains below-average numbers of mutations and hence my brain was able to develop properly, therefore you should mate with me, because my high-fitness-brain is likely to be passed on to your children.”

Miller (2000, 2011) has argued that human intelligence, too, is a “fitness indicator,” analogous to the bowers of bowerbirds and the tails of peacocks. Like any signal, signalers can deceive their receivers. Therefore, the signal has to be reliable and hard to fake (see Zahavi 1975). Hence, the traits that evolve through sexual selection are typically very different from normal survival adaptations. In particular, sexually selected traits are usually characterized by:

1. Higher phenotypic and genetic variation.
2. Positive correlations with other fitness-relevant aspects of an animal, such as parasite resistance, longevity, and body symmetry.
3. They can evolve quickly due to the runaway interplay between display of the trait and the preference for it (Andersson 1994; Miller 2000; Miller and Penke 2007).

All of these attributes fit human intelligence well (see Prokosch et al. 2005).

Hence, a strength of the sexual selection perspective on intelligence is that it can account for facts about human intelligence not accounted for by other models. For example, that intelligence is highly heritable, meaning that about half of the observed variation in intelligence across people are attributable to genetic differences (Plomin and von Stumm

2018). Another example is that intelligence in men is related to sperm quality (Arden et al. 2009), indicating that intelligence is associated with other conceptually unrelated but fitness-relevant traits. Furthermore, and more straightforwardly, intelligence is sexually attractive and one of the most desired traits for long-term sexual partners for both sexes (Buss 1989; Geher and Miller 2008).

Sexually selected traits in the animal kingdom often portray large sex differences, typically with males competing by showing off conspicuous displays and females choosing the best fit males (although this is sometimes flipped around, depending on which sex invests more in the offspring). Among humans, there are no sex differences in *general* intelligence (Jensen 1998). However, the evolution of fitness indicators does not *require* that one sex displays a sexually selected trait and that the other prefers it. Human mate choices are often best described by *mutual mate choice* (MMC) – both sexes are choosy about their mates, and both men and women select for intelligence (Stewart-Williams and Thomas 2013). However, the average fitness payoff for *showing off* high intelligence might still be higher among human males (Miller 2011). If the latter scenario is the case, it would result in high-intelligence men having more high-quality offspring and low-intelligence men being kept out of the mating game entirely, causing more variance in intelligence and general fitness among men. Indeed, this is the observed pattern among humans: There is greater variance in intelligence among human males (Deary et al. 2003; Stewart-Williams and Thomas 2013), with the consequence that there are slightly more men with extremely low and extremely high intelligence.

The fitness indicator model is a very unlikely explanation for why intelligence started to evolve in several *Homo* species (and in other mammals) in the first place. This is because, in general, traits that evolve into fitness indicators are selected (e.g., by female choice) for their hard-to-fake complexity and hence high mutational target size, but the trait is typically arbitrarily chosen (Keller 2008; Miller 2011). That these evolutionary events arose independently across species is therefore unlikely.

Moreover, some argue that the coevolution between language, sociality, and cognition alone can account for why the human brain expanded so quickly and hence regard sexual selection as explanatory superfluous (Pinker 2010). Future empirical research and analysis of genomic data will help shed light on how important or unnecessary the fitness indicator model is in explaining the evolution of human intelligence.

Conclusion

Intelligence, the ability to learn, reason, and solve problems, can predict many fitness-relevant life outcomes such as educational achievement, income, and health. There is still much to learn about the nuts and bolts of intelligence. However, connectionism and other approaches in cognitive science have shed some light on how neural circuitry can process information.

There are several models on why intelligence evolved in humans. Some highlight the mastery of the hostile forces of nature, such as finding food and keeping warm (ecological dominance), as a tool for social deception, competition, and cooperation (social brain), and that intelligence evolved for the purpose of displaying fitness in mate competition (fitness indicator).

The models on the evolution of intelligence are not always competing perspectives but rather different pieces of the puzzle that belong together (e.g., Flinn et al. 2005). It is nevertheless scientifically useful to differentiate them to derive clear testable predictions, in order to find out where they compete and where they align (Dunbar 1998). For example, one study found that human-sized brain and bodies were predicted by a model where individuals faced selection pressures that was 60% ecological, 30% socially cooperative, and 10% between-group competitive (González-Forero and Gardner 2018) (the fitness indicator model was not included), suggesting that several models are important but to different degrees.

The fitness indicator model can potentially explain why intelligence evolved so quickly and is sexually attractive and highly heritable and why it correlates with other fitness-relevant traits.

However, simpler models are probably better accounts for how the evolution of intelligence in the *Homo* line got started, and it is still debatable if sexual selection is superfluous or essential in explaining the existence of our big and costly brains.

Definition

Intelligence testing is a collection of tasks designed to measure cognitive capacities such as abstract reasoning, ability to solve problems, and ability to acquire knowledge, which may be the most important elements. The specific structure of this test depends on the definition of intelligence adopted by each psychometrician. Snyderman and Rothman (1988) reported that psychologists and educational researchers reach a general consensus supporting the validity of IQ testing.

Introduction

The precursor of intelligence tests was Francis Galton, the genius of diverse disciplines such as anthropology, statistics, geography, and psychology. He made the first attempt to establish standardized tests to assess one's intelligence. Galton believes that intelligence is inherited, thus there may exist a correlation between intelligence and some observable physical traits, such as visual acuity, reflexes, muscle grip, and head size. After collecting a large number of data on a variety of physical variables, he failed to demonstrate any such correlation (Carroll 1993).

Although Galton's work is quite illuminating for the intellectual testing boom in the twentieth century, later researchers turned back to the traditional viewpoint that intelligence is correlated with one's behavior and performance instead of physical traits. In 1905, French psychologist Alfred Binet and psychiatrist Theodore Simon developed first formal intelligence tests, the Binet-Simon Tests. The Test consisted of 30 cognitive subtests including measures of language skills, memory, reasoning, digit span, and psychophysical judgments. In the 1908 revision, Binet and Simon added nonverbal tests and applied the year scale, each test was assigned to the age level at which most children performed it successfully. The Binet-Simon scales have served as both a model of form and source of content for later individual intelligence tests (Boake 2002). Internationally, the most widely used intelligence tests are the Stanford-Binet Intelligence Scales and the Wechsler-Bellevue Intelligence Scale. The Stanford-Binet, revised from the original Binet-Simon Scale by psychologist Lewis M. Terman at Stanford University in 1916, extended the age range into adulthood and, most important, adopted intelligence quotient (IQ). The battery of Wechsler Intelligence Scale (1939) contains different versions for different age groups, that is Wechsler Adult Intelligence Scale (WAIS 1955), Wechsler Intelligence Scale for Children (WISC 1949), Wechsler Preschool and Primary Scale of Intelligence (WPPSI 1963) (Wechsler 2008). Wechsler's major contributions were not the

subtests themselves but rather the technical innovations of deviation scores, combining verbal and performance tests into a single scale, and selecting the adult standardization sample by occupation (Boake 2002). For various reasons, mostly the validity of rating person's intelligence and various psychological abilities, these two scales have achieved almost monopoly status in individual intelligence testing. However, these intelligence tests and their underlying definition of intelligence are not the most optimal framework to study intelligence from the perspective of evolutionary psychology. To do so, we focus on the theory of general intelligence and its relationship with evolutionary psychology in the following parts of this article.

Spearman (1904) investigated previous studies referring to various mental tests and argued that many cognitive abilities those were claimed to be unrelated by former researcher because of lacking adequate system of investigation, were actually related. He employed the factor analysis to testify the correspondence between the tests. The correlations between mental abilities are consistently positive, which indicates that there is a general foundation underlying these mental abilities. This common factor, namely, general intelligence or *g* factor, is rooted in many forms of intellectual activity such as in-school Cleverness, out-of-school Common Sense, Sensory Discrimination, and Musical Talent. Besides *g*-loaded components, every specific task contains a specific factor.

When the evolutionary psychology meets *g* factor, it is easy to draw the picture of the information-processing mechanisms. When our ancestors deal with multiple survival problems, such as finding food, shelter, or a mate or detecting danger, it is more economical to assume that we use multiple, overlapping sets of processes for each task, rather than thinking of each of these tasks as being solved by an independent, encapsulated piece of neural machinery, hard-wired for this purpose (Mackintosh 2000). Evolutionary psychologists are also concerned about whether intelligence is adaptive, and if it is, how it evolved, what its biological basis is? And, why

are there such individual differences in human intelligence, especially in IQ tests? The *g* factor theory may be the best framework of intelligence testing to answer these questions. According to Kanazawa (2004), general intelligence originally evolved as a domain-specific adaptation to solve evolutionarily novel problems. Through genetic mutations, our ancestors adapted successfully to solve problems such as mate selection, raising offspring, and navigation, which may be the *g* factor with past adaptive significance.

There has been a historical debate about the biological basis of general intelligence, particularly the relationship between intelligence and brain size. Some researchers reviewed the evidence regarding the relationship between intelligence and craniometrics, like head length, breadth, and weight, and argued that the relationship between brain size and general mental ability is now a well-established and widely-accepted fact (Bouchard 2014; Mackintosh 2000). The correlations between IQ scores and brains size is about 0.30. Besides, a number of studies shows that the *g* factor exists in a wide range of species, including mice, dogs, birds, and primates (Bouchard 2014). Since *g* has been shown to be correlated with brain size, it is natural to wonder the relationship between *g* and the structure and function of brain regions. Many neuroimaging studies have been devoted to studying the neural mechanisms of intelligence. A profound review published by Jung and Haier (2007) summarized the fruitful results and proposed the Parieto-Frontal Integration Theory (P-FIT) of intelligence, which report a striking consensus suggesting that variations in a distributed network predict individual differences found on intelligence and reasoning tasks.

Some critics argue that, Intelligence should not be adaptive because it is an individual variable (Borsboom and Dolan 2006). Adaptation is universal, a constant trait shared by all members of an ethnic group; In contrast, there are significant genetic individual differences in intelligence. Some individuals are more intelligent than others. These critics argue that adaptation and genetic

individual differences are mutually exclusive. These critics clearly have a deep misunderstanding of the nature of adaptation. Evolutionary adaptation can also be a variable of individual differences. In fact, most adaptations show individual differences.

There is another problem for concern. In the construction process of mental tests, the internal consistency procedure demands the selected items should be positively correlated with the total score of all the items in pool of all the tryout group. This process is inevitably affected by the tryout group's genetics and yields a test which is not representative of the item universe, resulting in a genotype-item interaction which have a solid and largely forgotten history of research in testing (Harrington 1997).

[Behavioral plasticity vs. natural selection](#)

Definitions

Natural selection is the main mechanism that brings populations to new adaptive optima when the environment changes, but intelligence may also contribute by helping individuals devise behavioral solutions to the novel challenges.

Introduction

Environmental conditions where organisms live are changing continuously, often creating mismatches between current phenotypes and those that would be optimal under the new circumstances. These mismatches may be reduced through evolutionary responses, provided that there is enough standing genetic variation for natural selection to act upon. However, animals can reduce adaptive mismatches through yet another mechanism: their “intelligence.” By enhancing plastic behavioral responses, intelligence can place the population close to the new adaptive peak with no need of genetic change. In this sense, intelligence can be seen as an alternative to natural selection. The present chapter describes how intelligence allows dealing with environmental changes, in which scenarios it should be an alternative to natural selection and what are the potential consequences for the evolutionary diversification of animals.

What Is Intelligence?

Intelligence is a slippery concept. From an ecological perspective, however, intelligence can be operationally defined as a domain-general cognitive ability of animals to devise plastic behavioral solutions to novel or unusual ecological problems. This definition thus includes advanced cognitive abilities, like causal reasoning, insight, self-awareness, and theory of mind but also less advanced abilities such as trial-and-error learning, associative learning, and behavioral inhibition. Intelligence should be seen as a complex adaptive system that may vary both qualitatively and quantitatively across individuals, species, and superior clades.

How Behavioral Plasticity Helps Dealing with Environmental Changes?

Like other mechanisms underlying plasticity, the intelligence of animals is thought to be an adaptation to cope with environmental changes

(Allman 2000; Sol et al. 2016). Intelligence can help animals develop new learnt behaviors (i.e., innovations) or modify behaviors already present to solve problems individuals have never or rarely experienced before, including periods of food shortages, irruption of novel predators, or sudden changes in climatic conditions (Sol 2003). Woodpecker finches (*Cactospiza pallida*), for example, build tools that allow them to consume caterpillars from wood crevices. However, this technique only replaces the more usual gleaning technique when seasonal droughts drive insects into crevices. By buffering individuals against environmental changes, intelligence enhances individuals' survival when the environment changes, bringing the population into the realm of attraction of the new adaptive peak (Price et al. 2003). Unlike natural selection, however, the response is rapid and often reversible.

Intelligence as Alternative to Natural Selection

If behavioral responses are enough to move a population close to a new adaptive peak, this should hide genetic variation from natural selection and hence inhibit evolutionary change. This is the so-called Bogert effect. Huey et al. (2003) illustrate it with a hypothetical example of selection on temperature regulation of a lizard distributed along an altitudinal gradient. Being ectotherm, if the lizard uses the environment randomly with respect to factors that influence body temperature, those individuals living at higher altitude will be selected toward progressively lower “optimal” body temperatures, as temperature decreases with altitude. However, if the lizard actively adjusts its behavior to the local thermal conditions, for example, by occupying shaded habitats at low altitude but more open habitats at high altitude, the mean optimal temperature will be similar regardless of altitude.

Despite the widespread influence of the Bogert effect, it is unlikely that behavioral responses completely replace natural selection. Losos et al. (2004), for example, showed that although *Anolis* lizards shift to use safer places when exposed to

predators, this change in behavior does not prevent natural selection to alter their morphology. Even in humans, who are masters in protecting themselves from the external environment by constructing and managing their own niches, natural selection is still acting (Barreiro et al. 2008).

When Intelligence Is More Important than Natural Selection?

Natural selection is ultimately the mechanism that brings the population's genotype to a new adaptive optimum when the environment changes and hence explains how organisms adapt to their environment. However, if intelligence functions to buffer individuals against novel ecological challenges, it may sometimes play a stronger role than selection in helping reduce adaptive mismatches, at least in the short term. This role will depend on both the degree of intelligence of the animal, which determines the extent to which individuals rely on behavior to solve ecological problems and the extent to which the new selective pressures can be dealt with behavioral adjustments. Moreover, it may also depend on the life history of the animal. All highly intelligent animals – like primates, cetacean, ravens and parrots – are long-lived. One reason is that developing a large brain and the behavioral skills needed to survive takes time, and only long-lived animals can afford it. Yet, a long-lived strategy reduces the power of natural selection both because it increases generation time (delaying genetic changes) and decreases population density (reducing standing genetic variation and the probability of new mutations, and increasing stochastic loss of beneficial mutations). In long-lived species, therefore, intelligence should often be more influential than natural selection as a mechanism to reduce adaptive mismatches when the environment changes, at least in the short term.

There are other scenarios where natural selection alone is less likely to bring the population close to a new adaptive peak. High variation in food resources over time and space, for example, makes natural selection to fluctuate in direction,

making adaptive specialization less likely. Under this scenario, intelligence may act as an alternative to natural selection by enhancing the individuals' ability of exploiting a wide array of foods (Ducatez et al. 2014).

Can Plastic Behaviors Promote Evolutionary Diversification?

The existence of the Bogert effect may lead to think that evolution should proceed more slowly in animals with enhanced behavioral plasticity. However, this is not necessarily the case if plastic behavioral shifts expose animals more frequently to new selective pressures. A change in behavior, like learning to exploit a novel resource, is likely to expose individuals to a new set of selection pressures favoring those mutations that improve individual's proficiency. This idea, called "behavioral drive" hypothesis (Wyles et al. 1983), is supported by two lines of evidence. The first is the observation that changes in behavior generally initiate changes in other phenotypic traits. The second is that, according to some studies (e.g., Sol and Price 2008; Wyles et al. 1983), animals with high propensity for behavioral innovation tend to evolve at a faster rate than those with less propensity. Although changes in behavior followed by morphological and physiological adjustments may be a potent force in driving evolution toward novel directions, the existence of the Bogert effect suggests that intermediate level of plasticity should be optimal to produce a peak shift (Price et al. 2003).

Genetic Assimilation

While a new behavior derived from intelligence can influence evolution of other traits by making individuals interact with the environment in novel ways, the behavior itself is learnt and hence cannot be selected. However, the behavior can later become genetically encoded via natural selection through a process called genetic assimilation. This only requires that the likelihood of producing the

behavior depends on a set of heritable traits (like appendages to manipulate objects or cognitive abilities to adopt the appropriate motor actions) and that individuals that are better at using the behavior attain higher fitness. If these conditions are met, natural selection will increase the frequency of individuals possessing the combinations of traits that predispose to perform the behavior. After many generations, individuals will end up looking like if they have an innate ability to do so. Genetic assimilation helps thus understanding how complex behaviors may become genetically encoded.

Conclusion

No organism can totally escape from the influence of natural selection. Yet natural selection is not all-powerful, and some degree of plasticity is always necessary in an ever-changing world. Intelligence functions to buffer individuals against novel ecological challenges, often playing an antagonistic role to selection. However, intelligence and natural selection cannot be simply seen as alternative mechanisms. Under certain conditions, both processes can jointly contribute to facilitate phenotypic change.

Introduction

The primary function of language is communication. Speakers and listeners make adjustments in order to accomplish their communication goals. This interaction begins when children are neonates as they smile, coo, and establish eye contact with caregivers (e.g., mothers, fathers, siblings, aunts, grandparents, etc.). Language is dynamic rather a final product. Language is an instrument for social interaction and speaker intents (what the speaker wishes to communicate). Pragmatics is the study of speaker intentions, conveyed messages, and listener interpretations (See discussion on pragmatics).

A brief review of language acquisition and how theoretical perspectives have evolved is presented. The behavioral approach was first presented by Skinner in “Verbal Behavior” (1957). According to Skinner, language learning depends on environmental variables, i.e., imitation, practice, and selective reinforcement of language structures. Language is gradually accumulated. Parents are crucial because they model the appropriate utterances. Parents also shape the child’s utterances until they are grammatically correct. This approach has been criticized because Skinner (according to Chomsky): (1) ignores the content of language learned; (2) children seem to acquire language repertoires far quicker than behavioral learning can account for; (3) children produce novel utterances; and (4) parents rarely correct their children’s productions.

The psycholinguistic/syntactic approach was developed by linguists in the late 50s and early 60s. Influential among this group was Chomsky. According to Chomsky (1965), the human brain contains an internal mental plan to understand and generate sentences. Children are born with an innate linguistic mechanism (i.e., the Language Acquisition Device or LAD). According to Chomsky, the LAD is activated by exposure to linguistic input. The LAD contains a set of rules or general principles for forming sentences, and procedures for discovering how language principles apply to the particular child. Chomsky focused on language being innate with universal features (i.e., a universal grammar) found in all languages; thus, all children were said to possess an internal and innate ability with the brain being pre-wired for language. This approach is criticized because Chomsky treats language as if it occurs independent of thought, cognitive development, and external factors.

Vygotsky, a Russian psychologist, espoused the theory that social development, social interaction, and play are important features of cognitive and language development in children (Vygotsky 1962). Vygotsky viewed social interaction as the prime factor in children’s learning. Wosensdregt and Smith (2017) state that the biological evolution of language is genetically transmitted. However, cultural evolution is transmitted through social learning. And subsequently, it can be said that pragmatics is crucial to social learning, language development, and cognition.

Pragmatics views language within the context of interaction with others. Child–caretaker interactions are seen to be the originating force for language learning. McLean and Snyder-McLean (1999) summarize the pragmatic model in four steps: (a) Language is acquired if and only if the child has a reason to talk. The child has learned (or not learned) that he/she can influence their environment through communication; (b) Language is acquired as a means of acknowledging existing communication functions, i.e., language supplements and replaces existing, less effective communication methods; (c) Language is learned in dynamic social interactions involving the child and an older, more mature language user. This occurs in the child and

other's environment; (d) The child is an active participant in the communicative exchange process and must contribute to it in a manner that allows for the child to benefit from the interaction. Hence, language development is a social, interactive process that also includes cognitive development.

The neurological approach states that all language and cognition is reflected in neurological brain structures. The developing brain in infants and children is about making neuronal connections. Neural cells must connect with other neural cells in the early stages of brain development (a stage labeled as mass migration or neural cell proliferation). Neural cells reach their final destination (i.e., making a connection with other neural cells) with the help of radial glia that spans the entire length of the neural tube. Defects in migration can result in neurological conditions such as epilepsy, mental handicaps, etc. Address selection is where the brain fires the neurons down a pathway, but not selectively, hence all the connections "light-up." The brain strengthens certain connections through repetitive use (i.e., from external stimulation) and eliminates random connections (i.e., pruning). The brain, thus, selects strong, appropriate connections and prunes less efficient and weak connections. This begins and occurs in the womb.

Experience (from external stimulation) drives maturation and development. With experience from the environment, neuronal cells can refine their circuits or connections and influence which connections are stabilized and which connections are lost. Learning is about neuronal connections. The temporal lobe, Wernicke's area, inferior parietal lobe, and the frontal lobe anterior to Broca's area are larger in human beings. Consequently, these areas are important for language and cognition. The temporal lobe is the seat of auditory processing (listening and comprehension). The auditory association area known as Wernicke's area is also important to the use of language.

Evolution-Based Theories

Evolution-based theories state that over time humans have evolved to learn language, not

because we have language acquisition devices (built-in devices), but rather our brains have evolved from previous brain structures. Evolution-based theories stress the relation between how the brain and language have evolved over time in different species, how they develop in children, and how adults perform language functions. In humans, speech and language has developed from brain structures and brain functions based on action recognition and action production (Rizzolatti and Arbib 1998).

In the brain, mirror neurons are activated when an action is performed or when the said action is observed. "These neurons are called mirror neurons because the observed action seems to be "reflected," like in a mirror, in the motor representation for the same action of the observer" (Buccino et al. 2004, p. 371).

The human brain evolved to recognize actions of others as a survival mechanism. Mirror neurons in monkeys (premotor area, anterior to the primary motor area) correspond with actions and observations of the same action the F5 area. Gesture recognition and observations of gestures also appears in humans in the F5 area (which is part of Broca's area (Rizzolatti and Arbib 1998). Buccino et al. (2004) also report that in the F5 area there are mirror neurons associated with the implementation and observation of mouth actions. It is speculated that Broca's area (important for speech production) evolved from F5. Thus, what is seen is that humans evolved actions, observation of those actions, and possibly speech from mirror neurons. The left inferior frontal gyrus (Broca's area), inferior parietal lobe, and posterior middle temporal gyrus involve action recognition, speech, and language functions (Rizzolatti and Arbib 1998). In conclusion, Rizzolatti and Arbib state that language evolved from an initial ability to recognize actions and which later evolved into language.

Stages of Language Development

Language develops along predictable developmental stages. All children experiment with language as active participants. Children learn

linguistic forms that easily fit into their current communication strategies. Children rely on similar sound patterns and environmental contexts to learn linguistic and nonlinguistic forms. Counter to Chomsky, attempts by parents to correct children's syntax is ineffective. And, children vary in the amount of spontaneous imitation that they do. Communicative language milestones are as follows:

1. Birth–1 month – the child uses different cries to express desires/needs or displeasure (i.e., differentiated cries).
2. 2–3 months – the child coos, pleasurable noises; open vowel-like sounds; smiles, squeals; and pitch changes appear.
3. 4–6 months – the child engages in sound play; consonant-like sounds, single syllable-like sounds; and engages in babbling.
4. 6–8 months – the child engages in reduplicated babbling (repeated consonants and vowels, e.g., ba-ba-ba); begins to look at objects that are named; and begins to imitate sounds.
5. 9–10 months – the child uses jargon (sounds like words) and imitates adult speech if the sound is in their repertoire.
6. 11–17 months – the child uses true words (the words are symbolic); gestures; understands “no”; and starts to label familiar objects/people.
7. 18 months – the child uses up to 50 words; combines 2 to 3 words; and understanding progresses rapidly.

Child-Directed Speech (CSD)

Child-directed speech is language directed at younger or less mature language users. It was formerly referred to as “motherese” or language directed by mothers to children. However, it was found that fathers, family members, older siblings, and caregivers also utilized this type of language. CDS typically occurs from 0 to 20 months (Paavola-Ruotsalainen et al. 2018).

Child-directed speech is when the caregiver perceives the child's communication and responds accordingly. During routinized social

activities, the caregiver interprets the child's communication and attributes meaning to the exchange (e.g., “Oh yes, that is a doggie”). This attribution on the caregiver's part is known as perlocutionary effect. The caregiver follows and maintains the child's focus (i.e., joint focus of attention). This joint focus communicates that what the child is communicating is important and reinforces the behavior to be repeated.

CDS consists of simplified syntax, and an exaggerated prosody adapted to the child's levels. Joint attention is shared attention by the child and adult. In addition, “here and now” language aligns with use of familiar words. Child-directed speech is more influential when the child is at the one word stage. Attention following is more important than attention redirections at 18 months of age. CDS also depends on the speaker's own language abilities.

A direct, high interactional style is when the caregiver attempts to control the child's behavior, gives commands, and/or redirects the child's attention. The direct, high interactive style is used extensively in the Anglo-American culture. It is characterized by: (a) Children are seen as equal conversational partners, on the same level as adults; (b) Speech is child directed; and (c) Parents are actively involved in speaking with their children.

An indirect, low interactional style is passive in terms of the caregiver's involvement. Some cultures refer to this style as the “look and listen” approach. It involves watching, understanding, and trying stages. Specifically, the phases or stages include

1. **Watching:** The look and listen phase. The child observes language use and interactions. Receptive processing is involved. Multiple exposure to the utterance and its use is key to learning.
2. **Understanding:** The child tries to process information and make sense of the world and how language is used.
3. **Trying:** This phase is divided into passive trying and active trying:
 - (a) *Passive trying* is mental rehearsal of the utterance and use of language. This is

characterized by mental practice and repetition of practice.

- (b) *Active trying* is when the child attempts the utterance and its use by speaking, i.e., physical practice. The active trying phase is not attempted until near mastery of the utterance is achieved.

Caregivers may employ any of the following strategies:

Context mapping: Using words to describe objects, actions, and events that the child is observing [similar to Brice-Heath's 1982 label quests and event casting].

Bridging: Relating one word used in one context to another new context.

Modeling: Showing use of a particular structure, behavior. Forced imitation is not required. Modeling may be paired with imitation; however, it does not require it.

Prompting: Providing some sort of cue to what she/he is trying to say. This may include saying part of the word, giving the word, or some other sort of clue.

Questioning: Purposely trying to elicit a response through a question.

Recasting: Changing the ungrammaticalness of an utterance while preserving its meaning. This is similar to modeling.

Repairing: Recasting or repeating the utterance in order to seek clarification.

Acknowledging. Any response to show that the listener is following the conversation.

Expansions: Making the utterance more grammatically complete.

Extensions: Adding new information to the utterance. Extensions can be added on to an expansion.

Conclusion

Language development is multifaceted and multiphasic. It appears that language abilities have evolved from earlier brain structures; yet, environmental stimulation plays a key role in furthering brain growth. In sum, language

development is about social interaction and communication.

Definition

Interference refers to the impaired ability to remember an item when it is similar to other items stored in memory.

Introduction

It was John A. Bergstrom who started to study the phenomena associated with interference. But it was the work of G. E. Müller, a German experimental psychologist, that inspired many other psychologists to become interested in interference. In 1894, Müller and Schumann observed that the learning of the second list of items interfered with the memory of the first list (reviewed in Dempster and Brainerd 1995). This observation was extended and studied in greater detail by Müller and Pilzecker in 1900, and the phenomena was called retroactive interference (or retroactive inhibition).

For the next 70 years, psychologists proposed many theories to explain forgetting associated with interference. Researchers describe interference as the competition between items that share a common retrieval cue (Anderson and Neely 1996). A retrieval cue is a clue or prompt that is used to trigger the retrieval of specific memories. Thus, if a retrieval cue connected with more than one item, it might make these items more susceptible to interfering with each other and less likely to be recalled.

The Most Important Phenomena in Classical Interference Research

Retroactive Interference

Retroactive interference (or “retroactive inhibition”) refers to the phenomenon that newer memories would interfere with the retrieval of previously learned memories.

Müller and Pilzecker were the first to study retroactive interference around 1900. In their fundamental experiments, tasks of different characteristics were added into the intervals between original learning and recalling, and it

was found that some interpolated conditions were followed by poorer recall than others. The phenomenon of such new learned materials interfering with the retention of previously learned material was termed by them “Rückwirkende Hemmung”, which should be translated as “retroactive inhibition” (reviewed in Britt 1935). Moreover, several factors have been concluded that can increase the magnitude of retroactive interference, such as the similarity between materials and the unfamiliarity of the previously learned material (Postman and Underwood 1973).

Proactive Interference

Proactive interference (or “proactive inhibition”) refers to the phenomenon that memories learned previously would interfere with the retrieval of newer memories.

The pioneer in the field of proactive intervention is Benton Underwood. In his studies, participants were asked to learn a list of paired words and to recall them after 48 h. After that, a new list was learned on the following day, followed by several additional lists. The learning and recall of each list were completed before a new list was learned. The results showed that the greater the number of previous lists learned, the greater the forgetting of the latest learned list. It was explained that the increasing decrements in recall were caused by the proactive interference from previous lists, and it was further discussed that the Ebbinghaus curve of forgetting was also due to interference from materials learned previously (Underwood 1957).

Researchers conclude that the magnitude of proactive interference depends on the categories of newer and older materials, the depth of original processing (i.e., materials learned more thoroughly may be less susceptible to proactive interference), and the length of the time interval between learning trials (i.e., longer intervals result in less proactive interference).

Of the two typical types of interference, retroactive interference causes more problems during learning and has a stronger impact (Edwards 2010). And retroactive interference is more obvious at short retention intervals, but at long

retention intervals, the influence of the proactive interference will be greater.

Output Interference

Output interference refers to the interference of the act of recall with the retrieval of the learned information. Tulving and Arbuckle (1966) conducted the first systematic study of output interference. Participants were presented with lists of paired associates in which the digits 1–10 were the stimuli and common words were the responses. In the recall tests, participants were asked to recall the words according to the randomly presented stimuli. Results showed that the recall performance declined with the increase in the sequence of stimuli. In subsequent studies, researchers used categories as the cues of recall tasks and asked participants to recall the given words. The results also supported the finding of output interference (e.g., Roediger and Schmidt 1980).

Furthermore, output interference could happen in not only short-term memory but also long-term memory. The recall of organized information from long-term memory has a detrimental effect on subsequent recall. Such kind of output interference effect is dependent on the size of the input categories and the amount of time allowed for recall (Smith 1971).

Based on the findings of output interference, Anderson et al. (1994) found that retrieving a subset of items from a category caused the forgetting of other items from that category. This phenomenon similar to output interference was referred to as retrieval-induced forgetting, which inspired a new wave of research.

Conclusion

Interference is a notion closely related to forgetting, and it is believed that interference is caused by competition among items that have a common retrieval cue. The most important phenomena in classical interference research are retroactive interference, proactive interference, and output interference. Interference effects also exist in other psychological fields, such as cognition and motor skills.

standard deviation. In a one sample t-test, a researcher sample is compared to a claim made of the population mean. In an independent samples t-test, researchers compare two sample groups against each other. Finally, when using a dependent sample t-test, researchers compare the means of various paired scores and then compare those means against a null hypothesis.

Analysis of Variance (ANOVA)

An ANOVA compares two group means against each other. The ANOVA is essentially an extension of an independent samples t-test, just on a grander scale. The two main types of ANOVAs are the one-way ANOVA, which only compares one independent variable against one dependent variable. For example, you could look at running and how it could elevate levels of happiness. In a two-way ANOVA, researchers compare two independent variables against one dependent variable. An example of this would be researchers looking at running AND gender and its effects on elevated levels of happiness.

Conclusion

There are many statistical tests used in psychological research, and this was just a brief overview of the main tests. Researchers use t-tests and ANOVAs primarily when looking for statistically significant evidence when trying to disprove a hypothesis. Attempting to read and decipher the meaning of results in peer-reviewed may cause one to become dismayed; however, interpreting these results and discovering which test was used is rather easy.

Interstimulus Interval

Androulla Ioannou and
Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

Interstimulus interval can be defined as the time interval between the end of one stimulus presentation and the onset of another stimulus presentation.

Introduction

The concept of interstimulus interval is frequently encountered within processes of non-associative learning, specifically habituation and sensitization Petrinovich (1984).

Experimental Research on Interstimulus Interval

Interstimulus interval experiments were extensive under the work of Davis (1970) on habituation of the acoustic-startle response in the rat. Generally, through Davis's series of experimental studies it was demonstrated that the length of interstimulus interval, as well as variability (regularity), determines habituation in animals. The author compared the responsiveness of two groups of rats to a 50-ms, 120-db tone of 4000 Hz during pretest, training, and posttest periods. During both the pretest and the posttest periods, both groups of subjects received 300 tone exposures at intervals of 2, 4, 8, and 16 s, the intervals being scheduled in an irregular order. During the training period, both groups received 1000 tone exposures; however, the interval between stimuli was 16 s in one group and 2 s in the other group. Among other findings, greater reduction in responsiveness was observed in the group who received stimulation every 2 s.

In the second experiment, startle responsiveness was lower following training with regular as opposed to variable interstimulus intervals. Simply put when interstimulus interval is longer and constant, habituation is greater. Also Davis (1970) reported a quite an interesting finding; when rats were tested at 1 min or 24 h later with a variety of interstimulus intervals, habituation was greater for the group that was trained on the 16 s interstimulus interval schedule suggesting thus that short-term and long-term habituation processes may be distinguishable on the basis of the presentation and the intervals between stimuli. Specifically, it was demonstrated that short interstimulus intervals were involved in the progression of short-term habituation, while long interstimulus intervals were involved in the promotion of long-term habituation. Also, apart from the fact that high frequency stimulation leads to more rapid response decrement, it results in faster spontaneous recovery as well.

Similarly, Groves and Thompson (1970) noted that increased frequency should lead to increased habituation in the "S-R" pathway, but in the "state" pathway it would lead to increased sensitization. All the aforementioned experiments considered together are indicative of the importance of interstimulus interval making it obvious that it can have a major effect on learning; it may delay or improve learning. Lastly, the organism's ability to determine the interval and duration of sensory stimulation is central to sensory processing; therefore impairments in that domain are likely to interfere with the process of learning.

Conclusion

Variations in the time between the presentations of one stimulus to the next have a determinant effect on the forms of non-associative learning; habituation and sensitization and that the occurrence of long-term and short-term habituation are dependent upon the length of interstimulus intervals. Further manipulation of interstimulus intervals will provide valuable information regarding disruptions in learning processes or even suggestions as to how to enhance learning.

Definition

The evolutionary genetic conflict describing the causes and consequences of alternative alleles at particular genetic loci being selected oppositely in the two sexes, such that one allele at a given locus

will pose fitness benefits to male individuals but fitness detriments to female individuals, and vice versa for the alternative allele at that locus.

Introduction

Intralocus sexual conflict is the genetic conflict between the sexes (Lande 1980; Bonduriansky and Chenoweth 2009; van Doorn 2009). As opposed to interlocus sexual conflict (IeSC), where the conflicting traits of males and females are underlain by different genes (i.e., loci), intralocus sexual conflict (IaSC) occurs when the same genetic locus or loci control the trait in conflict between males and females (Arnqvist and Rowe 2005).

The term “conflict” refers to the outcome of selection in one sex being detrimental to the survival and/or reproduction (i.e., fitness) of individuals of the other sex. Thus, “conflict” over a particular trait refers to selection on that trait operating in opposing directions in males and females. This is known as sexually antagonistic (SA) selection and is the driver of sexual conflict (be it IaSC or IeSC). SA selection is explained more thoroughly below and in the coming section(s). For now, know that selection is differential fitness among individuals. If a particular version of a given trait benefits the bearers’ fitness, it is said to be under positive selection. Likewise, the particular genetic variant (i.e., allele) of the gene responsible for such a trait is also said to be under positive selection. So when a trait or gene experiences SA selection, it means that the version of the trait or gene that benefits male fitness also detriments female fitness and vice versa for the alternative version of the trait/gene. Thus, IaSC is the conflict that ensues due to SA genetic variation for fitness.

Genetic variation refers to the different versions/alleles of a given gene. So, specifically, IaSC occurs when one allele of a given gene benefits male fitness but detriments female fitness and the other allele of that gene benefits female fitness but detriments male fitness. Hence, “*intralocus*,” i.e. the conflict, is over the

genetic variation *within* a gene. One allele of such a gene experiences positive selection in males but negative selection in females and vice versa for the other allele. The gene is therefore under SA selection. But selection ultimately operates on the traits produced by genes, so if a gene is experiencing SA selection, it must mean that the trait it produces is under SA selection. One version of the trait (owing to one allele) benefits the fitness of male individuals but detracts that of female individuals, and the other version of the trait (owing to the other allele) benefits the fitness of female individuals but detracts that of male individuals. There can be many such genes exhibiting IaSC, but the conflict is over the genetic variation (alleles) within each gene.

So how does this happen? How does a gene that underlies a trait that is expressed by both males and females come to exhibit two alternative alleles, each posing benefits to one sex but detracts to the other? In answering that question, we must first think of the fate of new mutations in a population. If the mutation is 'good' for individuals of both sexes, relative to the original allele, then bearers of that mutation (i.e., that new allele) will survive and/or reproduce more than individuals bearing the original/old allele of that gene. The new mutation/allele will therefore become more frequent each generation, as its successive bearers continue to out-reproduce those lacking the mutation. Over generations, that new allele will eventually become fixed, i.e., everyone in the population will have the new allele and the original allele will die out along with its bearers. Alternatively, if the mutation is 'bad' for individuals of both sexes, relative to the original allele, bearers of that new allele will survive and/or reproduce less than individuals bearing the original allele, and the mutation will quickly be eliminated/lost from the population. It will die out with its bearers. But if a new mutation/allele is good for individuals of one sex and bad for those of the other (relative to the original allele), this places the gene under SA selection. Each allele is selected for via one sex but against in the other. Which allele is ultimately lost and which is fixed depends on the strength of positive and negative

selection acting on the two alleles in each sex. If the strength of positive and negative selection acting on each allele is equal in magnitude (but opposite in sign) in males and females, then both alleles of such a gene will be maintained in the population indefinitely (Kidwell et al. 1977). Even upon deviations from perfect symmetry in the strength of sex-specific selection at SA genes, there are a variety of conditions under which both alleles will still be maintained indefinitely over generations (e.g., Kidwell et al. 1977 and other examples given below). This has important implications for the maintenance of genetic variation for fitness, a concept addressed in more detail below.

So IaSC is an outcome of SA selection *and* a genome that is largely shared across the sexes (Lande 1980; Arnqvist and Rowe 2005; Bonduriansky and Chenoweth 2009; van Doorn 2009). So how likely are these two precursors? How likely is it for the above scenario to happen? With the exception of the sex chromosomes (accounting for a small proportion of genes), the genome is definitely mostly shared by both sexes, so presumably most genes are used by both sexes and are therefore vulnerable to SA mutations (described above). As for whether or not there will be SA selection, as long as there are two sexes that reproduce in fundamentally different ways, individuals will experience sex-specific selection for traits that disregard, and are inevitably bad for, the fitness of individuals of the opposite sex (Kokko and Jennions 2014). So there will be SA selection, at least acting on traits, as long as there are two sexes. And since much of the genome is being used by both sexes, the same genes in males and females encode many of those SA traits. So IaSC would seem unavoidable. Indeed, theoretical models predict the inevitability of IaSC and show its profound influence on the evolutionary trajectory of sexually reproducing populations (Connallon and Clark 2014). Furthermore, since most of a population's genetic variation that is either good or bad for both sexes should be rapidly fixed or lost, respectively (see above), most of the remaining standing genetic variation for fitness should be SA (Connallon and Clark 2012).

An Empirical Example

There are plenty of examples of wild and laboratory populations exhibiting significant levels of SA genetic variance for fitness (e.g., Chippindale et al. 2001; Fedorka and Mousseau 2004; Brommer et al. 2007; Foerster et al. 2007; Berger et al. 2014). However, the best empirical evidence/example for a specific gene experiencing IaSC comes from Barson et al. (2015). Their study of Atlantic salmon revealed a single gene explaining 39% of the observed variation in age at reproductive maturity. This is a very large percentage of the variation to be explained by a single gene for a trait that is likely governed by many genes. There are two versions/alleles of this gene in their study population. Being homozygous (i.e., having two of the same allele, one from each parent) for one of the alleles caused individuals to grow to sexual maturity quickly and consequently have a smaller adult body size – traits that are beneficial to males, but not females (see below). Being homozygous for the other allele caused individuals to grow to sexual maturity more slowly and consequently have a larger adult body size – traits that are beneficial to females, but not males (see below). However, in a heterozygous state, having one copy of each allele, individuals were *not* simply of intermediate growth rates and sizes; instead, one allele exhibited dominance over the other in a sex-specific manner. That is, which allele was dominant over the other in heterozygous individuals depended on the sex of the individual. The male-benefit allele was dominant over the female-benefit allele in males, and the female-benefit allele was dominant over the male-benefit allele in females (Barson et al. 2015).

This is an especially exciting example of IaSC for three reasons. First, it is one of the few, if not the only, definitive empirical examples of a specific gene exhibiting IaSC. As mentioned above, there is plenty of empirical evidence for SA genetic variance natural populations, but identifying specific genes underlying SA genetic variance has been challenging. Second, the traits (largely) controlled by this gene – growth rate and size – exhibit a widespread and well-understood life history trade-off (i.e., grow fast/be small or grow

slow/be big). Thus, it advances our understanding of this classic life history trade-off, and it provides solid empirical evidence for the common assumption that life history traits are vulnerable to IaSC (described below). Lastly, this is the first empirical example of sex-specific dominance partially resolving IaSC, consequently maintaining both of the population's allelic variants of this SA gene. Sex-specific dominance was the first of many conditions predicted to maintain alternative alleles at SA loci when the strength of selection is not perfectly equal between the sexes (Kidwell et al. 1977; Fry 2010). As discussed above, even if the strength of selection is only slightly different between the sexes, the allele that is favored by the sex experiencing stronger selection will become fixed, and the other lost, if it were not for additional mechanisms acting to stabilize the maintenance of both alleles at SA loci. Knowing that such mechanisms can, indeed, help to maintain alternative SA alleles in wild populations provides confidence that IaSC is widespread in nature, posing fundamental consequences to a variety of evolutionary processes.

Consequences and Outcomes of IaSC

The consequences of IaSC for evolutionary outcomes are potentially vast. The prevalence of some of these outcomes (e.g., the near ubiquity of sex chromosomes in sexually reproducing species) supports the notion of IaSC being inevitable. In other cases, the implications of a given outcome (e.g., the potential for extinction) can be so drastic that it deserves further research/understanding regardless of how common it might be. Some of these consequences and outcomes will be covered in more detail in later sections, and some of them are far beyond the scope of this section. Still, in the coming paragraphs, I will try to at least introduce most of these.

The Maintenance of Genetic Variation for Fitness

As hinted at above, SA genetic variation can act to maintain a population's genetic variation for fitness. One of the most long-standing questions in evolutionary biology has been: What maintains genetic variation for fitness? Evolution requires

genetic variation. There must be alternative alleles producing alternative versions of traits in order to provide some variation among individuals upon which selection can act. But even with genetic variation at the start, as selection gradually fixes or eliminates certain alleles, that genetic variation gradually disappears. So how does evolution continue in the face of selection? There are many explanations for what maintains genetic variation for fitness in the face of selection, and one of those explanations is that selection is actually SA. Again, SA selection on a gene can maintain both alternative alleles over generations, and there are many plausible mechanisms that enhance the likelihood of maintaining SA genetic variation (e.g., Kidwell et al. 1977; Fry 2010; Arnqvist et al. 2014). This could effectively maintain a population's genetic variation for fitness depending on what proportion of the population's standing genetic variation for fitness is SA. Remember, since the genetic variation that is either good for both sexes or bad for both sexes should be rapidly fixed or lost, respectively, a population's standing genetic variation for fitness is expected to be disproportionately SA (Connallon and Clark 2012). Thus, IaSC may have a very prevalent role in the maintenance of genetic variation for fitness in wild populations and therefore may help to explain one of evolutionary biology's most long-standing questions.

Sex-Chromosome Evolution

Another major research focus in evolutionary biology is sex-chromosome evolution. SA loci play an important role in the evolution of sex chromosomes (van Doorn and Kirkpatrick 2007; Blaser et al. 2014). Sex chromosomes, among other things, determine the sex of an individual. They do this via the action of sex-determining genes/loci. So there are sex-determining genes that determine the sex of an individual, e.g., one version of the gene *produces* females and the other *produces* males. And there are SA genes, which you are familiar with by now – one version of the gene *benefits* females and the other *benefits* males. There is selection for SA mutations to occur on the same chromosome near sex-

determining genes (Jordan and Charlesworth 2012). This is because if a SA mutation occurs (by chance) near a sex-determining gene, the two versions of those two genes that are on the same chromosome will tend to be inherited together. The value of this for lucky individuals/lineages is that, for example, if a male-determining allele (at a sex-determining gene) is co-inherited with a male-benefit allele (at a SA gene), this will produce males that are particularly good at surviving and/or reproducing as males. Likewise, the same is true for females possessing female-benefit genes. Such individuals/lineages will out-reproduce those with mismatched sex-determining and SA alleles (e.g., males with female-benefit alleles). So there is selection for SA mutations/genes to occur near sex-determining genes due to the benefits posed to individuals of a given sex of being 'good' at being that sex (Jordan and Charlesworth 2012). This in turn generates selection for the homologous pair (i.e., mother/father pair) of chromosomes to stop recombination – to stop exchanging genetic material during meiosis – so that 'good' combinations of sex-determining and SA genes are always co-inherited together (Bull 1983; Rice 1996) or, in other words, so that male-benefit alleles are only passed on to sons and female-benefit alleles are only passed on to daughters. This arrest of recombination causes such 'neo-sex-chromosome' pairs to diverge further and further in genetic sequence and functionality over many generations. For example, the familiar X and Y chromosomes of many species are extremely different in size, gene content, and mutation load. The proximity and chronology of sex-determining and SA mutations, as well as the potential arrest of recombination that follows, influence which chromosomes are coopted for sex determination (i.e., become sex chromosomes), and whether or not they will be kept indefinitely as the sex chromosomes or cyclically abandoned for a new set of neo-sex chromosomes over and over (van Doorn and Kirkpatrick 2007; Blaser et al. 2014). So IaSC plays an important role in sex-chromosome evolution and therefore an important role in the evolution of most eukaryote life.

Sexual Dimorphism

Sexual dimorphism (sex differences beyond reproductive organs) is another large domain of research within evolutionary biology, but also in medicine and conservation, and fields outside the biological sciences (e.g., psychology, sociology, philosophy). In many species, males and females are far more different from each another than are two members of the same sex from different species. IaSC both promotes and constrains sexual dimorphism. The sexes reproduce in fundamentally different ways and therefore accrue and maximize their reproductive fitness in fundamentally different ways (Arnqvist and Rowe 2005). Recall the classic life history trade-off discussed above – grow fast/be small or grow slow/be big. Females tend to take time to incubate offspring and therefore require long, reproductively active lives in order to maximize their reproductive success. They also tend to benefit from being big in cases where larger body size enables greater fecundity (Fairbairn et al. 2007). They tend to achieve long life and large body size by having lower metabolic rates, slower growth rates, and allocating resources toward things like immune system function and somatic tissue maintenance. Alternatively, males tend to maximize their reproductive success by fertilizing as many females as possible. They typically benefit from growing fast in order to reach sexual maturity before their competitors and being fast, strong, and/or aggressive adults so as to win the competition for mates. They tend to achieve this by having higher metabolic rates, faster growth rates, and allocating resources toward reproductive traits, potentially at the expense of being able to invest in their immune system and/or somatic tissues, consequently having shorter life spans (the so-called ‘live-fast/die-young’ life history strategy). Thus, the sexes tend to exhibit different physiologies, metabolic rates, growth rates, body sizes, mating behaviors, patterns of aging, etc. (Arnqvist and Rowe 2005; Fairbairn et al. 2007). These life history traits are commonly underlain by the same genetic bases in males and females since they are some of the most basic features of an organism, but they are also commonly sexually dimorphic (Arnqvist

and Rowe 2005; Fairbairn et al. 2007). So how does this happen?

Using mostly the same genome, males and females of a given species must achieve very different life histories in order to survive and reproduce successfully. They accomplish this in a number of ways (e.g., cellular and hormonal processes during development, epigenetic processes, phenotypic plasticity, etc.), but the most common and most well understood of these ways is via the few small genetic differences between them, the sex chromosomes. As discussed above, the sex chromosomes tend not to recombine and therefore diverge in sequence and functionality over time. Thus, the sex chromosomes can enable sexual dimorphism in two ways. The first is via sexually dimorphic traits being underlain by genes located on the sex chromosomes (i.e., sex-linked genes). For example, in an XY sex-determining system, the product of genes on the Y chromosome will only ever appear in males, and the product of some genes on the X chromosome may require two copies in order to produce enough product (e.g., RNA or protein) to carry out their function, meaning that such a gene will only be effective in XX females. But sex linkage only accounts for a relatively small percentage of the genes in the genome of a given species. The second and more prevalent mechanism via which sex chromosomes enable sexual dimorphism is sex-biased (and sex-specific) gene expression. The sex chromosomes house, among other things, regulatory genes that can turn other genes throughout the genome on or off or up or down; and since they are sex chromosomes, this enables sex-specific gene regulation. This can allow individuals with the ‘wrong’ SA alleles for their sex to survive and reproduce better than they otherwise could have. In this way, sex-specific/biased gene expression can alleviate some of the genetic conflict between the sexes. So, IaSC sets the stage, i.e., generates selection, for the conflict to be resolved so that the sexes can achieve sexual dimorphism and maximize their reproductive fitness, which would essentially allow the sexes to evolve more independently from one another than they could otherwise. Thus, the genetic conflict that constrains sexual dimorphism in the first

place thereby generates selection for other genes to enable sexual dimorphism. One can therefore consider every sexually dimorphic trait of a given species as evidence of a previous IaSC that has been (partially) resolved. But the conflict cannot be completely resolved. New SA mutations can always arise, and many genes are not regulated by genes on the sex chromosomes. So IaSC is expected to still be a severe constraint on achieving sexual dimorphism (Lande 1980), as has been shown in many species, from fruit flies (Griffin et al. 2013) to humans (Stearns et al. 2012), preventing the sexes from achieving their sex-specific fitness optima.

The Tragedy of the Commons

As mentioned, IaSC can cause individuals with the ‘wrong’ alleles for their sex to perform poorly, and this can affect a population’s viability/persistence. Specifically, if females of a population perform poorly then the population may decline in numbers, which can lead to inbreeding depression and extinction (Kokko and Brooks 2003). Females are the limiting factor in population growth rate. This is because, as mentioned above, females take time to incubate offspring, whereas males can fertilize many, many females in a relatively short period of time. Further, females typically receive enough sperm from a single mating to fertilize their entire life’s worth of eggs. Thus, there need only be relatively few fertile males in a population to fertilize all the females, whereas the fewer females there are the fewer offspring a population will produce. When a population’s genetic variation for fitness is largely SA, the ensuing IaSC inevitably causes some males and females to have the ‘wrong’ alleles and to perform poorly (hence “conflict”). When this happens to males, it has very little effect on the population, since relatively few fertile/good males are absolutely needed for a population to persist. Alternatively, when some females do poorly the population as a whole will produce fewer offspring. A population’s offspring production will be proportional to the number and fecundity of its females. If each subsequent generation produces fewer offspring with fewer fecund females, the population could enter into a

downward spiral of declining population size, which can lead to inbreeding depression from breeding among related individuals, and potentially population extinction (Kokko and Brooks 2003). For example, using a wild caught SA population of seed beetles, we have shown that genotypes exhibiting relatively high-male/low-female fitness exhibit relatively low potential to contribute positively to population growth rate (Berger et al. 2016a). This was interpreted as a consequence of both IaSC and IeSC (see second sentence of this article, above). Genotypes with the alleles that are good for males are those with the alleles that are bad for females (i.e., IaSC), and genotypes with high male fitness feature aggressive males that physically harm females upon mating attempts and copulation, lowering female lifetime offspring production (i.e., IeSC; Berger et al. 2016a). In our example IaSC is not acting alone, but it can nevertheless play an integral role in the fate of populations.

Same-Sex Sexual Behavior

Lastly, IaSC provides an explanation for same-sex sexual behavior such as homosexuality in humans. It should first be clear that there are vast mechanistic differences between same-sex sexual behavior in something like an insect (e.g., same-sex mounting, which is observed in many species in nature) and homosexuality in humans, other mammals, birds, or fish, for example. The former can have rather simplistic potential explanations (e.g., strong selection in males to mate frequently and weak selection against brief mistaken encounters), whereas the latter certainly entails far more complexity in terms of the neurological, biochemical, and physiological bases of attraction and conscious behavior. Nevertheless, the SA underpinnings of something like same-sex mounting in an insect and homosexuality in humans have been shown to exhibit strikingly congruent quantitative and population genetic bases (Gavrilets and Rice 2006; Camperio Ciani et al. 2015; Berger et al. 2016b). Camperio Ciani et al. (2015) nicely reviewed the literature on this topic, concluding that, at least for male homosexuality, the predictions from IaSC (modeled by Gavrilets and Rice 2006) fit the available relevant pedigree and

population data well, supporting a SA genetic basis for male homosexuality in humans. I urge readers to refer to Camperio Ciani et al. (2015) for a more thorough and careful handling of this topic. I will only summarize some of their key points here. Two key observations of the data on male homosexuality in contemporary human populations stand out: (1) it persists at low frequency, and (2) pedigree analyses reveal an elevated likelihood of homosexual males in family lineages with particularly high maternal-line female reproductive success. Thus, the genetic factors/alleles involved must be stable at low equilibrium frequencies (i.e. robust to alleles becoming fixed or lost (recall discussions above on the maintenance of SA genetic variation)) and there must be some maternal-line mode of inheritance. A two-locus population genetic model, consisting of one autosomal gene and one gene on the X chromosome, with SA selection, proposed by Gavrilets and Rice (2006), provides the best fit to these two key empirical observations (Camperio Ciani et al. 2015). Thus, one might generate the following mechanistic hypothesis based on IaSC: female-benefit alleles causing females to be particularly attracted to males experience positive selection because this results in females having relatively more offspring, and those same alleles have the same effect (attraction toward males) in their male offspring. However, *female* homosexuality in humans is more difficult to explain – it is less dichotomous than male homosexuality, it is more variable over the course of individuals' lifespans, and it is more vulnerable to environmental/social influence (see Camperio Ciani et al. 2015).

Trans-generational SA epigenetic processes possibly offer an explanation that is even more accurately representative of the observed data and is also capable of accounting for female homosexuality (Rice et al. 2012). Furthermore, this would also explain why identifying a particular gene or genes reliably associated with homosexuality in humans has been so difficult, as epigenetic processes would not be revealed by genetic association studies. By this mechanism, SA epigenetic marks ("epimarks," e.g., methyl tags that bind to DNA and affect gene expression) masculinize or

feminize the genome during development and are typically erased and reapplied upon fertilization according to the sex of the zygote (Rice et al. 2012). Mistakes or epimarks that escape erasure can result in the genome of males/females being feminized/masculinized, respectively (Rice et al. 2012). This explanation does, however, move us away from IaSC per se, as the mechanism is not entirely genetic (so we are no longer talking about "loci" but rather "marks" on loci), but as mentioned, the epimarks in this model *are* necessarily SA (Rice et al. 2012).

IaSC *can*, however, explain male *and* female same-sex sexual behavior in other animals, for example, insects. We have shown, using the same SA population of seed beetle discussed above, that lineages artificially selected over generations for increased male-male mounting behavior exhibited higher female lifetime reproductive success (Berger et al. 2016b). Reciprocally, we also revealed that lineages artificially selected over generations for increased female-female mounting behavior exhibited higher male lifetime reproductive success (Berger et al. 2016b). The evidence implicates IaSC over the genetic components of both male and female same-sex sexual behavior (Berger et al. 2016b).

Conclusion

As the sexes achieve/maximize their reproductive fitness in fundamentally different ways, they benefit from different versions of the genes they share. This is the genetic conflict between the sexes known as IaSC. It is an inevitable outcome of having two sexes share the same genome. This conflict constrains sexual dimorphism, inhibiting males and females from achieving their sex-specific fitness optima, and therefore generates selection for other genetic mechanisms to enable sexual dimorphism. As there are many mechanisms that act to maintain alternative alleles at SA loci over generations, IaSC may play an important role in the maintenance of genetic variation for fitness in natural populations. SA loci also play a central role in sex-chromosome evolution, meaning IaSC has heavily influenced the

evolution of the eukaryotic branch of life on Earth. IaSC has implications that reach far beyond the study of evolution. For example, its implications for population viability and extinction are informative for conservation biology.

Perhaps the broadest appeal of IaSC is its capacity to inform us about the fundamentals of sex differences, which poses insights to fields as diverse as medicine, psychology, sociology, and philosophy. Although IaSC is understood well from a theoretical perspective, we are still building its empirical foundation. Many studies have provided evidence of populations exhibiting sizeable proportions of SA genetic variance for fitness. Recently, the most convincing case of a specific gene exhibiting IaSC was identified by Barson et al. (2015), an empirical finding that was supportive of much of theoretical expectation for IaSC. As the intrigue with this genetic conflict between the sexes continues to grow, more research will continue to uncover more details, eventually revealing just how widespread and influential IaSC has been, is, and will be to biological evolution.

Intralocus Sexual Conflict Across the Genome

Elina Immonen

Department of Ecology and Genetics, Uppsala University, Uppsala, Sweden

Synonyms

Cross-sex antagonistic pleiotropy; Genetic conflict between the sexes; Sexual antagonism;

Sexually antagonistic genetic variation; Sexually antagonistic polymorphism

Definition

How the loci harboring alleles with opposite fitness effects on the sexes are distributed across the genetic material in a cell: the sex chromosomes, autosomes and organelles such as mitochondria.

Introduction

Female and male reproductive roles are different, and consequently many phenotypic traits are selected in opposite directions in the two sexes, a process called sexually antagonistic (SA) selection. How traits respond to SA selection in each sex is, however, not straightforward. Depending on species, males and females possess a majority or all of the same genes. The shared gene variants (called alleles) cause a strong genetic correlation between the sexes, and the opposing selection pressures therefore lead to a tug-of-war, termed “intralocus sexual conflict,” over optimal expression of phenotypes (Bonduriansky and Chenoweth 2009).

An important consequence of SA selection is that it can maintain genetic variation, and therefore diversity, in a population that could otherwise quickly disappear if alleles were similarly selected in the sexes. Population genetic models have been developed to understand the conditions under which this can happen. A chief outcome of such models is that it matters where in the genome loci harboring SA alleles reside. Regions with asymmetric inheritance between the sexes, such as sex chromosomes and organelle genomes, can accumulate SA alleles more easily than autosomes because they are more often (or exclusively) exposed to selection in one sex than in the other.

Sex Chromosomes or Autosomes: Model Predictions

An influential early work by Rice (1984) concluded that SA alleles are more likely to be

maintained on the X and Z sex chromosomes in male (e.g., in mammals) and female (e.g., in birds) heterogametic systems, respectively. This is the case for recessive alleles beneficial to the heterogametic sex (males with XY, females with ZW) but harmful to the opposite, homogametic sex. Such alleles need to be recessive because in that way their effects are always visible to selection in the benefitting sex, but protected from being selected against in the disfavored sex when paired with a dominant, unharmed allele (which masks the effect of a recessive allele in heterozygotes). On the other hand, dominant alleles that benefit the homogametic sex are also likely to accumulate on the X and Z. While such alleles can readily be selected against in the disfavored sex, what helps with their invasion is that X and Z linked alleles occur more often in the favored sex (2/3 of the time in fact, because the homogametic sex has always two copies) allowing more opportunities for selection to keep the alleles in the population. In line with the Rice model, experimental work using *Drosophila melanogaster* has demonstrated a disproportionate role for the X chromosome harboring SA variation (Gibson et al. 2002). Also recent work on humans finds that most of SA loci associated with sex differences in survival map to the X chromosome (Lucotte et al. 2016).

There are, however, conditions that can make autosomes also attractive to the accumulation of SA loci. Rice (1984) stated that autosomes can maintain SA variation if selection acting on each sex is (nearly) equal in strength. This is an unstable situation and hence happens rarely. However, Fry (2010) expanded the possibilities by concluding that if the dominance effect of alleles is different in each sex – so that the favorable allele will always increase the fitness of the focal sex when paired with a disfavored allele – it will lead to balancing selection maintaining both female- and male-benefit alleles. Such a dominance reversal occurs in an autosomal locus *vestigial-like family member 3* (*VGLL3*) of salmon, resolving sexual conflict over body size at maturation. Alternative alleles for early and late maturation are dominant in males and females, respectively, leading to heterozygotes that are identical in genotypes at this locus but express

different sizes at maturation to achieve optimal fitness in each sex (Barson et al. 2015). Other examples of autosomal SA alleles maintained by balancing selection include *arginine vasopressin receptor 1a* (*Avpr1a*) in bank voles, with roles in reproductive behaviors, and a gene *Cyp6g1* encoding cytochrome P450 in *Drosophila*, which confers resistance to DDT but also increases female fecundity while suppressing male mating success (Mank 2017).

Organelles Are Special

Organelle genomes can accumulate SA variation because they are uniparentally transmitted and therefore respond to selection only through the transmitting sex. For example, in most species only mothers pass on mitochondrial genomes. This allows mutations harmful to males to be maintained, especially when favored but even when they confer no fitness benefit to females (a phenomenon termed the “Mother’s curse”). Work on *D. melanogaster* shows how mitochondrially encoded enzyme cytochrome oxidase II damages sperm development (Patel et al. 2016). Male fertility problems in humans and mice are also often associated with impaired function of mitochondrial genes (Nakada et al. 2006).

The Genomic Legacy of Sexual Conflict

Sexual conflict shapes genomes leaving molecular characteristics that can tell us about both present-day and past antagonistic selection. Intralocus conflict selects for a genetic resolution, leading to sex-specific genetic architecture of traits that allows independent responses to selection in each sex. One way to achieve such a resolution is through evolution of sex differences in gene expression. Sex-biased gene expression (i.e., higher relative expression in one sex) can therefore be indicative of a history of SA selection acting on the transcriptional patterns of such loci. Compatible with the theory, there is excess of sex-biased genes in the sex chromosomes across taxa (Ellegren and Parsch 2007). The conflict

resolution via sex-biased expression may, however, be only partial: evidence from humans and flies shows that genes with moderate levels of sex-bias are still subject to ongoing SA selection (Cheng and Kirkpatrick 2016).

Evolution of homomorphic sex chromosomes (X and W) is also a resolution to the conflict. Sex chromosomes are the product of evolution for recombination suppression between the X and Y (or Z and W), and studies on fish suggest that selection on reduced recombination has occurred to maintain male-benefit alleles on the Y chromosome (Wright et al. 2016). The conflict is resolved because Y-linked genes are simply never present in females. In species where parts of the Y chromosome still recombine with X, the positive feedback-loop between accumulation of SA variation and subsequent selection to expand the area under which recombination with X is suppressed is still ongoing (Mank 2017).

Conclusion

Sexually antagonistic loci can be studied using candidate gene approaches, gene expression analysis, and genome-wide association studies (GWAS). More recently, also population genetic methods have been applied to identify SA loci by testing how allele frequencies change due to sex differences in survival in humans (Cheng and Kirkpatrick 2016; Lucotte et al. 2016). Although these techniques have already provided important examples of SA loci and their genomic locations, many more need to be discovered to answer important open questions including how often the same loci are subject to antagonistic selection across populations and species, and, importantly, which phenotypes do the genes involved encode for. Sexually antagonistic selection truly is common and humans are no exception. With the democratization of the sequencing technologies this important field will continue to shed light into the outstanding question of how sexually antagonistic selection shapes the genomes of humans and other organisms alike.

Intrasexual Competition Between Females

Amanda Hahn and Benedict Jones
Institute of Neuroscience and Psychology,
University of Glasgow, Glasgow, UK

Intrasexual competition refers to competition between individuals of the same sex for access to mating opportunities (Andersson 1994) and is expressed through both direct aggression (e.g., physical combat) and indirect aggression (e.g., competitor derogation, self-promotion) (Campbell 2004; Vaillancourt 2013). Although direct aggression among women clearly does occur (Stockley and Campbell 2013), intrasexual competition among women more commonly takes the form of indirect aggression (Vaillancourt 2013). These indirect competitive strategies can act to increase a woman's own access to her preferred mate (e.g., through self-promotion) or decrease a rival's access to mating opportunities (e.g., through competitor derogation).

Self-promotion involves attracting attention to and enhancing one's own attractiveness, typically through the use of attractive clothing and makeup (Buss 1988; Grammer et al. 2004; Schmitt and Buss 1996). Self-promotion is an effective tactic for mate attraction due to the importance of physical attractiveness for men's mate preferences (Buss and Barnes 1986). Indeed, women frequently report using these self-promotion tactics to compete with rivals and attract members of the opposite sex (Cashdan 1998; Tooke and Camire 1991; Walters and Crawford 1994). By contrast, competitor derogation involves decreasing the appeal of a rival to members of the opposite sex (Buss and Dedden 1990). Competitor derogation can be achieved

through disparaging a competitor's appearance and through gossip or reputational damage, particularly related to the rival's fidelity or promiscuity (Vaillancourt and Sharma 2011). Additional derogation tactics include excluding a rival from peer groups and derisive actions aimed at lowering a rival's willingness to compete for mates (Campbell 2004). Competitor derogation is an effective tactic, with negative information about conspecifics predicting low attractiveness rankings of those individuals (Rucas et al. 2006). While women use both self-promotion and competitor derogation tactics, some research has suggested that self-promotion is used more often (Fisher et al. 2009).

Given that attractive individuals achieve greater mating success and are more successful at mate-poaching (Sunderani et al. 2013), these individuals pose a greater threat to mating opportunities and mate retention. Unsurprisingly, intrasexually competitive tactics are more often used against these attractive rivals compared to less attractive individuals (Arnocky et al. 2012; Massar et al. 2012; Vaillancourt 2013). For example, women are more likely to discriminate against attractive same-sex candidates in the workplace (Agthe et al. 2011), are less willing to introduce an attractive same-sex individual to their partner (Vaillancourt and Sharma 2011), and are more likely to have negative responses to a "sexy" rival than a conservative rival (Vaillancourt and Sharma 2011).

A growing body of research has suggested that female intrasexual competition is influenced by reproductive status, suggesting that women have a greater desire to outdo attractive rivals to obtain a high-quality mate when conception is possible. In line with this idea, intrasexually competitive behaviors have been shown to increase during adolescence (Archer 2004) and young adulthood (Hess and Hagen 2006; Massar et al. 2012). Conversely, intrasexually competitive behaviors decrease following menopause (Jones et al. 2011; Vukovic et al. 2009). This rise and fall in intrasexually competitive behavior parallels changes in general fertility across the life span (Dunson et al. 2002). In young adult women, intrasexually competitive behaviors have also

been shown to increase during the fertile phase of the menstrual cycle as compared to non-fertile phases (Beall and Tracy 2013; Durante et al. 2008, 2011; Fisher 2004; Haselton et al. 2007; Lucas and Koff 2013; but see Arslan et al. *in press*; Cobey et al. 2013). Research investigating the hormonal correlates of within-woman changes in intrasexual competitive behaviors has shown links to testosterone levels (Hahn et al. 2016; López et al. 2009). Priming intrasexual competitive motivations in women also increases testosterone levels in women (Maner and McNulty 2013; Ritchie and van Anders 2015).

Definition

Competition between males for access to females or the resources desired by females.

Introduction

Sexual selection leads to the development of traits and behaviors that improve reproductive success. Darwin recognized two types of sexual selection: intersexual and intrasexual selection. Intersexual selection occurs when one sex chooses which members of the opposite sex to mate with, while intrasexual selection occurs when members of the same sex compete for mates (Darwin 1871).

In many species, males compete through intrasexual competition to gain access to females. Critical work in *Drosophila* in the 1940s revealed that the mean number of offspring a male can produce increases with the number of mates he has, while the mean number of offspring a female can produce does not vary greatly and is not limited by access to mates (as long as there is at least one mate) (Bateman 1948). This finding also applies to mammals. For example, male red deer have more reproductive potential and greater reproductive skew than females. Some males will successfully fight for mates and produce ten times more offspring than a female will produce, while many males will sire no offspring at all (Lewin 1982).

This chapter will first provide an overview of the different forms of both direct and indirect male-male competition. It will go on to discuss how male-male competition relates to other forms

of sexual selection, and will conclude with a description of the role that intrasexual male competition has been proposed to play in human mating behavior.

Direct Intrasexual Male Competition

Contest Competition

Since females are usually the choosier sex, males often compete with one another directly for mating access. This competition has led to the evolution of a diverse array of weaponry among animals. For example, many deer and elk species in the family Cervidae have large antlers that can be used in direct competition during the mating season to gain access to females. Further, in many primate species, males have large canines that can be used as lethal weapons in contest competition. Perhaps unsurprisingly, in species where males have weapons, weaponry is often one of the most variable morphological traits within the population (Emlen 2008).

Direct male-male competition does not always have to end in a fight. Sometimes, species with the deadliest weapons have a reduced likelihood of sustaining injuries from contest competitions because weapon size is hypothesized to provide an honest signal of a male's fighting ability (Smith and Price 1973). Before any conflict occurs, a male can gauge the strength of his competitor and decide whether he will be able to successfully compete against him. As a result, some of the most common fights that occur between males are those where male weaponry is equally matched.

Dominance Hierarchies

In populations where individuals spend time together and have repeated interactions with others in their social group, dominance hierarchies may emerge as a product of male-male competition. Among different species, dominance structures can vary based on the strength, stability, and linearity of the dominance hierarchy. Often, males will compete directly with one another to achieve dominance. However, it remains unclear whether variation in strength and fighting ability between males or social constructs such as winner-and-loser

effects more strongly influence how dominance is determined in a social group. While the former hypothesis is well supported in the literature, research on baboons indicates that winner-and-loser effects may also play a role in the construction of dominance hierarchies (Franz et al. 2015).

In species that fight for dominance, high-ranking social status may serve several functions. Dominant males often have priority of access to resources, including females and food, which increases their reproductive success and may improve their health, respectively. Dominance hierarchies also create a social order that prevents individuals from having to constantly fight potentially deadly battles with conspecifics.

Just as weapon size is thought to signal strength in many male mammals, in species where males fight for dominance, dominant males will sometimes display a badge of status. Gelada males compete to be one-male unit (OMU) holders, with each OMU containing multiple females. Males that have an OMU have the reddest chest patches, with patch redness reflecting the number of females in the OMU (Bergman et al. 2009). In male mandrills, red coloration displayed on their face and anogenital region indicates social rank, and more fights occur between males of similar colors than those that show a large difference in red coloration (Setchell and Wickings 2005). Therefore, dominance hierarchies and badges of status provide mechanisms by which males can compete for access to females while limiting the number of potentially deadly contests.

Indirect Intrasexual Male Competition

Sperm Competition and Mate Guarding

Intrasexual male competition can also act indirectly. One common form of indirect intrasexual competition occurs through postcopulatory sperm competition. In species where females mate with several different males, the males' sperm compete to fertilize the female's gametes. In polyandrous and polygynandrous mating systems, males will have larger testes than in monogamous or polygynous mating systems (Harcourt 2005). In primates, the size of the testes is often related to the

mating system of the species: males in polygynous mating systems have smaller testes weights while males in polyandrous and polygynandrous mating systems have larger testes weights. In other taxa, such as insects, males in a polyandrous or polygynandrous mating system may have enlarged accessory glands to produce more seminal fluid (Mikheyev 2004). Finally, in species with a polyandrous or polygynandrous mating system, a male's ejaculate may form a copulatory plug that is made up of a coagulation of seminal fluid and prevents the sperm of other males from reaching the ova (Dixon and Anderson 2002).

In addition to sperm competition, another postcopulatory indirect form of intrasexual male competition is mate guarding. This form of competition is most common in taxa where multiple males mate with one or more females during the mating period or in cases where sperm is a limited resource. After copulation, a male may prevent other males from mating with the female or may prevent a female from seeking out additional mates. Mate guarding can be accomplished by staying close to the female for an extended period, postcopulatory mounting, extending copulation, or coalitionary guarding, depending on the species (Edward et al. 2015). Sometimes, only certain males in the population will guard females. This may be due to the fact that mate guarding is energetically expensive and affects a male's feeding time and energy balance (Girard-Buttoz et al. 2014).

Endurance Rivalry

Males can also compete indirectly prior to copulation. When reproductive skew is low in a polygynandrous group, several males may mate with several females over an extended period and reduce the amount of time they spend on other activities. In these scenarios, the males who spend the longest amount of time actively mating with females are the ones who sire the most offspring. For example, rhesus macaque males experience increases in their fat reserves prior to the mating season but during the mating season, males lose up to 10% of their body weight by focusing on mating and mate guarding rather than activities such as feeding (Bercovitch 1997).

Endurance rivalry is not limited to species with moderate reproductive skew. Elephant seals are one of the most sexually size dimorphic mammals with some males weighing more than three times as much as females. Over the 3-month reproductive season, a few of the largest males fight off smaller males to achieve high rank, defend large groups of females, and sire almost all of the offspring. While males compete directly, they also engage in endurance rivalry since females stay on land for the duration of the mating season while feeding occurs in the water. Reproductive success is greatest for males with the largest fat reserves and can invest in mating and mate guarding rather than feeding (Andersson 1994).

Alternative Reproductive Tactics

In populations where males experience a shallow reproductive skew, selection may favor the development of alternative reproductive tactics. These tactics include any behavior that is distinct from the most commonly used mating strategies and may be maintained by frequency-dependent selection, heterozygote advantage, or condition-dependent selection (Neff and Svensson 2013). For example, males may employ sneaking behaviors, morphologically resemble females, or mate guard their mates. These mating strategies enable males to avoid intrasexual conflict while gaining access to females.

Side-blotched lizards provide a notable example of alternative reproductive tactics. In populations where a majority of males occupy large territories and monopolize females, sneaker males secretively mate with females without having to compete with other males for territory thus increasing their reproductive success compared to males who cannot acquire territory and do not use this tactic (Zamudio and Sinervo 2000). In primate species such as Japanese macaques and Hanuman langurs, where males often live in multi-male multi-female groups, some males may choose to live alone or in all-male groups (Setchell 2008). These males will mate with females opportunistically during the mating season thus avoiding competition with dominant males in the social group.

Intrasexual Male Competition in the Context of Total Sexual Selection

Although intrasexual male competition and female mate choice are often studied in isolation, it is important to acknowledge the role that female choice plays on intrasexual male competition. In populations where mate choice occurs, the preferences of the female should influence the type of competition that occurs between males. If females require a home territory, males should compete for the resources that the female needs, such as land, rather than directly competing for females. In contrast, if a population is structured into one-male, multi-female groups, males should engage in contest competition with other males to gain access to these one-male units.

Intrasexual male competition may also influence mate choice. Some argue that, over time, weapons that were originally used for male-male competition may have become intersexual signals used by females to determine preferred mating partners. Further, in species that exercise female choice, direct intrasexual male competition may provide females with information about the strongest male and influence their mating preferences. This will reinforce selection on traits used in competition (Hunt et al. 2009).

Intrasexual male competition and female mate choice rarely act independently. To better understand the selection pressures on a male sexual trait, it is essential to determine total sexual selection on the trait (Hunt et al. 2009). Total sexual selection encompasses the strength of selection imposed on both sexes by competition and mate choice. When male-male competition and female mate choice interact on the same trait, the effects of these processes can be reinforcing, such that total sexual selection is similar to the strength of each selection pressure independently or opposing, with the resulting total sexual selection differing from either of the selection pressures on its own (Hunt et al. 2009). Intrasexual male competition and female mate choice can also act on different temporal scales. When male-male competition occurs prior to female mate choice, male-male competition will eliminate some of the phenotypes from which females can choose. When

the two processes overlap temporally, both processes select male traits from the same pool of phenotypes and some males may gain access to females by obtaining exclusive mating opportunities while other males gain access to females by displaying attractive traits (Hunt et al. 2009).

Intrasexual Male Competition in Humans

Over our evolutionary history, intrasexual male competition has been an important component of human behavior. One way to evaluate mating and social systems of the past and make assumptions about intrasexual competition is through studies of sexual size dimorphism. Since body size is heritable and helps males win contests, the larger the size dimorphism between male and female primates, the more frequently males compete directly for females (Andersson 1994). Our hominin ancestors, such as *Australopithecus* and early *Homo*, likely displayed a significant sexual size dimorphism. Over the course of hominization, however, this body mass dimorphism was reduced and modern human populations show a modest body mass dimorphism of about 15% (Smith and Jungers 1997). Humans have also lost the canine size dimorphism that is present in many primate taxa. However, since human females store more body fat than males, some have argued that fat-free body mass should be used to measure sexual size dimorphism. Using this method, the ratio of fat-free mass in males compared to females is 1.41, indicative of a significant, moderate size dimorphism (Lassek and Gaulin 2009). Thus, humans experience some degree of body size dimorphism that, while reduced compared to our hominin ancestors, highly suggests that males compete both directly and indirectly for access to females and resources desired by females (Triveres 1972).

Direct Intrasexual Male Competition

One method of intrasexual competition in human males is violence. Beginning early in life, males are more aggressive than females and more frequently engage in rough-and-tumble play (Ellis et al. 2008). Further, males generally have a

higher pain tolerance than females (Ellis et al. 2008). In the tribal Yanomamo society, males engage in contests that involve shouting matches and fights with clubs, axes, machetes, and arrows (Chagnon 1988). In a rural population in Senegal, Sereer wrestling is a traditional fight that occurs regularly in villages and winners often increase their access to mates (Llaurens et al. 2009). According to the Global Study on Homicide, 95% of the perpetrators and 80% of the victims of homicide are male (Caman et al. 2017).

As in primates, human males have also been proposed to compete directly through displays of dominance. Men of high status may procure more opportunities to mate and high status has been shown to be a necessity for women in a mate-screening process (Li et al. 2002). One suggested mechanism by which males display dominance is voice pitch. Studies indicate that when voice pitch is artificially lowered, men perceive these voices as more dominant than higher pitched voices (Puts et al. 2006). Further, men who believe they are dominant to another man will lower their voice pitch when speaking, while men who believe they are less dominant will raise their voice pitch (Puts et al. 2006). Among the Hazda, lower voice pitch has been suggested to increase reproductive success in males but not in females (Apicella et al. 2007). However, the relationship between voice pitch and dominance has recently come into question, with some arguing that it lacks evidence or is simply the product of an innate assumption that larger objects and organisms emit a lower pitch than smaller ones (Feinberg et al. 2019).

In addition to voice pitch, facial characteristics may also serve as a dominance display. Across two distinct cultures, men were considered more aggressive and of higher social status if they had a beard than if they were clean shaven and this sensitivity was stronger in men than in women. This may occur because beards increase the perception of the size of the jaw and length of the face (Dixon and Vasey 2012). Further, computer-manipulated masculinized faces are perceived by men as more dominant than feminized faces and a negative correlation exists between one's self-rated dominance and perceived dominance in masculine faces (Watkins et al. 2010a, b).

Indirect Intrasexual Male Competition

Men have been proposed to utilize two distinct alternative mating tactics: a “quality” strategy or a “quantity” strategy (Hirsch and Paul 1996). The former strategy usually involves long-term relationships, while the latter occurs over a much shorter time frame of a few months to a few hours. Through the “quantity” strategy, men attempt to gain access to a large number of females while minimizing costs and the potential for commitment using tactics that often involve threats and psychological pressure. Using the “quality” strategy, men attempt to ensure high partner commitment, paternity certainty, and female reproductive value using tactics such as resource expenditure and honest advertisement (Buss and Schmitt 1993; Hirsch and Paul 1996).

Men have also been proposed to compete indirectly for access to mates through mate guarding. The Mate Retention Inventory catalogs 19 tactics that males use to guard women such as calling at unexpected times and preventing a woman from going to events without her male partner (Buss 1988). These mate-guarding tactics are more commonly used when the male’s partner is young and attractive and when confronted by males who are more economically successful (Buss 2002). Failure to mate guard can result in reproductive costs such as providing parental investment to another man’s offspring and losing the female to another male.

Similar to many mammalian species, humans also employ sneaky copulation tactics and may engage in sperm competition. In a survey of Australians, 28% of men and 22% of women reported engaging in extrapair copulations (Simmons et al. 2004). The rate of extrapair paternity can vary greatly, ranging from 0.03% to 31.8% in a modest number of studies, with Western populations generally having lower rates than pastoral and tribal populations (Scelza 2011; Simmons et al. 2004). Consistent with the statistics above, male relative testes size is greater than expected for a monogamous species suggesting that sperm competition may occur (Simmons et al. 2004). Men have a higher percentage of motile sperm in their ejaculates when viewing a sexually explicit image depicting two men and one woman

than an image depicting three women, which has been proposed to suggest that evocation of sperm competition alters sperm composition (Kilgallon and Simmons 2005).

Conclusion

Intrasexual male competition occurs when males compete with one another for access to females or resources desired by females. This competition can occur directly, such as through contests, or indirectly through several methods including sperm competition, mate guarding, endurance rivalry, and sneaky copulations. Importantly, intrasexual male competition does not occur in isolation and intersexual competition often operates conjointly with intrasexual competition. Finally, over our evolutionary history, human males have had to compete for access to mates and modern males experience intrasexual competition that occurs both directly and indirectly.

Definition

Intrasexual rivalry is a driving force behind sexual selection. Men's intrasexual rivalry surrounds competition over reproductive opportunities and resources.

Introduction

Men's reproductive potential is higher yet more variable than that of women, owing to women's substantial (and men's relatively lower) obligatory parental investment. For ancestral men, outcompeting same-sex rivals for access to desirable and varied mating opportunities would have benefited their total reproductive success. Evidence of adaptations for increased intrasexual rivalry among men can be seen in modern human physiology, mating psychology, and related behaviors such as epigamic displays and aggression, which differ between sexes. Mating systems and other contextual factors influence sex differences in competition, such that male rivalry

is stronger in polygynous versus monogamous systems, and when female are abundant rather than scarce.

Male rivalry has been shaped over deep evolutionary time by *sexual selection* – or the variability among same-sex conspecifics in fertilizing the gametes of the opposite sex. Sexual selection is the driving force behind evolution (Darwin 1871) and is the product of two interrelated phenomena: *intersexual selection* and *intrasexual selection*. Intersexual selection refers to the nonrandom choice of mating partners between the sexes. Intrasexual selection refers to the competition between members of one sex for reproductive access to members of the other sex. Same-sex competitors exhibit morphological, psychological, and behavioral traits which directly bear upon their ability to attract mates (intersexual selection) and to defeat rivals in coopting and retaining reproductive access and resources. To the extent that the phenotypic qualities exhibited by individual organisms benefit their success in inter- and intrasexual competition for mates, those organisms will be more likely to produce viable offspring who will themselves be more likely to bear competitively efficacious traits allowing them to, in turn, outcompete intrasexual rivals lacking in those adaptive traits for mating opportunities.

In most species, intersexual selection is driven largely by females, who choose their mates carefully from the male population. Males, on the other hand, more often engage in intrasexual selection, vigorously vying for mating opportunity with selective females. Male intrasexual competition is so ubiquitous that in *The Descent of Man*, Darwin (1871) wrote “it is certain that amongst almost all animals there is a struggle between the males for the possession of the female. This fact is so notorious that it would be superfluous to give instances” (p. 143).

The sex difference in the frequency and ferocity of intrasexual rivalry can be understood in light of disparate obligatory parental investment between the sexes (Trivers 1972). Females produce a limited number of energy-rich eggs and males produce many energetically cheaper sperm (Trivers 1972). Females are limited by the number

of eggs and hence the number of offspring they can produce over their reproductive lives. Because females bear the heavier parental investment, they have the most to lose from making poor mating decisions and are thus selective in their mate choice (Trivers 1972). In contrast, male reproductive potential is limited only by the number of fertilizable females they can access. Yet because, on the whole, the number of offspring sired by males and females in the population is the same, successful males who reproduce with multiple females impose a significant cost upon other males, many of whom will thus be less-successful or will be shut-out from reproducing altogether. Accordingly, males more than females have evolved phenotypes oriented toward competing for mating opportunities.

Intrasexual Rivalry in Humans

Unlike the vast majority of mammalian species, humans tend to pair-bond, as evidenced by social monogamy, serial monogamy, and even pure genetic monogamy that has been observed across diverse cultures. This, coupled with substantial bi-parental care of offspring, has likely tempered sex differences in intrasexual competition. Men are also highly selective in choosing their long-term mates, and thus intrasexual rivalry among women is not uncommon. Intrasexual competition can take on many forms, which can be distinguished in terms of combat (i.e., contest) and noncombat competition. Humans exhibit a diverse menu of intrasexually competitive acts including direct combat (i.e., trying to physically threaten, dominate, injure, or kill a rival), verbal derogation of competitors, social manipulation, as well as many forms of noncombative self-promotion (i.e., trying to enhance the positive qualities of oneself, relative to same-sex others) (Buss and Dedden 1990).

Noncombative Tactics

Many of the noncombative tactics employed by men relate strongly to the mate-preferences of the opposite sex. For example, men more than women believe in the efficacy of, and more frequently utilize, tactics of intrasexual competition involving resource possession and display (e.g., driving

a fancy car, flashing money, buying women expensive goods, bragging about accomplishments), which correspond to women's relatively greater preference for mates who possess resources. Another related strategy that may be used during men's intrasexual competition is *derogation* of other men's financial resources, physical strength, and athleticism. Indeed when newlyweds were asked to self-report their use of derogation tactics as well as those used by their spouses, men more than women reported derogating a rival's strength (Buss and Dedden 1990).

Male Intrasexual Aggression

Men compete more violently than women in the domains of status, resources, and dominance. Wilson and Daly (1985) showed that homicidal conflicts in 1972 Detroit were prodigiously committed by men. These findings mirror those from semi-nomadic hunter-gatherer societies, such as the Yanomamo of Venezuela, where one in four adult males are killed by others individuals within their tribe or in wars with other tribes, with nearly half of all men over the age of 25 having participated in killing someone (Chagnon 1988). Aggression directed toward same-sex rivals may solve a variety of adaptive problems, including the coopting of resources, defense against attack (avoiding loss of status and resources), inflicting costs (on one end making rivals less desirable as mates through reputational damage; on the other end, eliminating them as a potential mate altogether by killing them), negotiating the status hierarchy (such as when Aché males who survive many club fights gain increased status, fear, and admiration), and deterring rivals from future aggression (by having a reputation as a dangerous or violent threat to rivals). The extent that male aggression exists within a culture or subculture hinges upon a variety of factors, such as the likelihood of retaliation and whether the aggression is situated within a "culture of honor," wherein failure to aggress upon being insulted can result in status loss.

At its core, men's intrasexual aggression is driven by efforts to achieve and maintain status, resources, and mating opportunity. To test this hypothesis experimentally, Griskevicius and

colleagues (2009) primed men with status and mating motives by exposing them to short stories. Results showed that status motives increased men's willingness to engage in direct aggression (face-to-face confrontation). Men's aggression was also increased by mating motives within the context of being observed by other men. Male sexual jealousy is also a driving force behind men's intrasexual violence, whereby over 90 % of same-sex killings involving "love triangles" are perpetrated by men and fewer than 10 % by women (Daly and Wilson 1988). Some researchers have observed links between male aggression, victimization, and mating outcomes. Arnocky and Vaillancourt (2012) found in a prospective longitudinal study that male adolescent indirect (but not direct) aggression was associated with being more likely to have a dating partner 1 year later.

Collective Male Aggression

Warfare and intergroup rivalry can also be understood within the context of competition for reproductive success. Greater male, relative to female, participation in organized collective violence is seen at various cultural and subcultural levels, from street-gangs to international warfare. Durham (1976) developed and tested a model showing that the costs of participating in collective aggression can be outweighed by its survival and reproductive benefits when access to scarce and valuable resources is at stake. Accordingly, men may have evolved psychological mechanisms enabling them to form coalitions centering upon perpetrating acts of aggression against outgroups with the goal of acquiring or protecting reproductive resources. For instance, among the Yanomamo, collective groups of men often raid neighboring tribes as acts of revenge, and also to forcibly take food and women (Chagnon 1988), suggesting that men form aggressive coalitions to coopt valuable reproductive resources and opportunities.

Adaptive Physiology for Competition

Men's adaptations for engaging in physical combat are well-exemplified by studies of sexual dimorphism in body size. In most sexually

reproducing species, males are substantially larger than females; sexual dimorphism in body size is owed greatly to intrasexual competition, whereby larger males often achieve greater mating success than smaller rivals (e.g., McElligott et al. 2001). Compared to other Hominids such as orangutans and gorillas, modern Humans exhibit relatively less sexual dimorphism in body size. It is important to note, however, that the relatively less extreme sexual dimorphism in humans (at least, in terms of body size) does not imply that observable physiological sex differences are somehow vestigial in relation to intrasexual competition. Indeed, Archer and Thanzami (2007) found that young Indian men with greater size and strength reported more frequent physical aggression in the previous year. Lassek and Gaulin (2009) examined the relationship between fat-free mass (FFM) and limb muscle volume (LMV) and mating success. Results showed that although FFM and/or LVM are positive predictors of daily energy intake and negative predictors of C-reactive protein and white blood cell count, indicating a tremendous physiological cost to production and maintenance of increased musculature, FFM and LMV were also predictive of men's total and past-year self-reported sex partners as well as age at first intercourse. Men's body size and strength also relates to various characteristic associated with intrasexual rivalry. Fessler et al. (2014) found that men's chest compression strength was inversely related to their perceptions of the size and strength of various rivals (supporter of a rival sports team or as a man armed with a handgun), suggesting that assessment of rival physical threat varies as a function of one's own strength. Male adolescents with more handgrip strength are also more likely to highly estimate their own fighting ability, which in turn predicted actual use of physical aggression (Muñoz-Reye et al. 2012).

Whereas physical size and stature may be implicit in men's ability to fight and to provide protection or resources, other associated morphological traits also relate indirectly to men's intrasexual rivalry as signals of their mate-value and/or formidability. For instance, men with lower

pitch voices are perceived as being more physically dominant and are also rated by others as being larger, more masculine, and older (see Puts et al. 2012 for review). In samples drawn from both the USA and from Hadza foragers, Puts and colleagues (2012) showed that various sexually dimorphic vocal parameters predicted men's body size, strength, testosterone, and/or physical aggressiveness. In North American samples, women have reported lower pitched men's voices as being more attractive, particularly during the fertile phase of the menstrual cycle, men with low-pitched voices report having had more sex partners, and Among Hadza hunter-gatherers, low voice pitch correlates with having more offspring (see Apicella et al. 2007).

For men, components of facial masculinity such as protruding cheekbones, large and well-defined chins, heavy brow bones, and facial hair might also be important correlates of rivalry among men (see Arnocky et al. 2014a for review). Bearded males are rated by women as being more masculine, aggressive, socially mature, and older (Neave and Shields 2008). Research has shown that a marker of facial width-to-height ratio predicted men's reactive aggression as well as aggression (in penalty minutes) among varsity and professional hockey players, and subsequent studies have linked the FWHR to achievement drive, self-reported dominance, and reduced likelihood of death from homicide involving direct physical contact (see Haselhuhn et al. 2015). Mueller and Mazur (1996) showed that cadets' facial dominance predicted subsequent status (in terms of promotions) later in their careers. Little and colleagues (2015) found that observers of facial photos of mixed martial arts fighters were accurate above chance in predicting the winners of fights, and that winners' faces were perceived as being more masculine, as well as stronger, and more aggressive. Women in this study also viewed winner faces as more attractive. Taken together, these findings suggest that men with masculinized somatic, facial, and vocal features may be more dominant, more aggressive, more successful in altercations, and are viewed by women as being more desirable, at least within the context of short-term mating.

Testosterone and Men's Intrasexual Rivalry

The common thread between all of the aforementioned morphological signals is that physical size and strength, deeper vocal pitch, and facial masculinity have all been shown to correlate with testosterone (T) – an androgenic hormone that produces male sex characteristics. T diverts resources away from immune functioning; accordingly, only men of sufficient immunocompetent condition can afford the cost of elevated T. A man's condition could therefore be assessed in his T-linked secondary sexual characteristics. T is important to men's intrasexual rivalry for at least two reasons: First, regarding *intersexual* selection, women should prefer men who exhibit features associated with increased T, given that men who can withstand the immunologic costs associated with developing these characteristics are healthier and thus better able to provide offspring with good genes, resources, and protection. Indeed, some evidence has suggested that males with more masculine bodies in terms of height, strength, and with more masculine voices, and faces are indeed healthier than their less sexually dimorphic conspecifics (see Arnocky et al. 2014a for review). T is also positively linked to sperm concentration and motility (Meeker et al. 2007).

Second, regarding intrasexual selection, T is a driving force behind male dominance and aggressive behavior. Archer (2006), in reviewing evidence pertaining to the challenge hypothesis (i.e., context-dependent increases in testosterone levels linked to aggression) in humans, suggested that T rises among young men who are challenged (e.g., men from "cultures of honor" who are insulted), as well as in men who are in a pre-competitive state (e.g., before a sporting match), and among winners of direct competition (e.g., following a successful competition or sporting match). Conversely, T is often shown to decrease among losers of competition (Archer 2006). Notably, T responses to intrasexual competition have been observed throughout the animal kingdom (Archer 2006), suggesting that context-dependent changes in T may serve important adaptive functions. It has been proposed that the costs associated with maintaining elevated T concentrations (e.g., decreased paternal care, increased risk for

physical injury/death, depressed immune function, increased energetic demands) may have led to a highly flexible endocrine system capable of rapidly modulating T in response to social challenges (Wingfield et al. 2001). Also, it has been speculated that acute changes in T within the context of competitive interactions may ultimately serve to fine-tune ongoing and/or subsequent competitive and aggressive behavior (Archer 2006). Consistent with this functional account of T reactivity, a growing body of evidence indicates that increases in T during competitive interactions positively predict aggressive behavior in healthy young men (see Carré and Olmstead 2015 for review). Recent research that acutely increases T concentrations through pharmacological challenge indicates that T rapidly increases amygdala and hypothalamic reactivity to angry facial expressions (Goetz et al. 2014). Importantly, these brain regions are rich in androgen and estrogen receptors and play a key role in the modulation of aggressive behavior (see Carré and Olmstead 2015). More recent work indicates that a single application of T to young men rapidly increases men's perception of their own facial dominance (Welling et al. 2016). Specifically, T led men to perceive themselves as more physically dominant, which ultimately may in part explain links between T and human aggression. That is, T may enhance men's perceptions of their own formidability, which may increase their willingness to engage in intrasexual competition with other men. Together, this body of literature suggests that high T men may be more competitively successful than low T men in domains of intersexual selection (especially for short-term mateships) and intrasexual rivalry. Men's intrasexually competitive behaviors are driven, at least in part, by real or perceived challenges to their reproductive fitness that are mediated by context-dependent changes in testosterone.

Contextual Influence on Men's Competition

The implementation and efficacy of intrasexually competitive tactics may vary depending on a number of factors including but not limited to (1) the mating system and individual mating goals, (2) the number of mates available locally,

(3) men's relative mate-value, and (4) ovulatory shifts in women's mate preferences.

Men's intrasexual rivalry is characteristically different in terms of tactics employed within short versus long-term mating contexts. For instance, Schmidt and Buss (1996) found that emphasizing their immediately available resources was judged as being most effective for men pursuing short-term relationships, whereas showing resource potential as well as derogating a rival's resource potential and achievements were judged as most effective for men pursuing long-term relationships (Schmidt and Buss 1996). Simpson et al. (1999) told men and women they would be competing with another same-sex individual for a date with an attractive opposite-sex person. While being videotaped, participants stated why the potential date should choose them over the competitor. Results showed that men who reported a more unrestricted sociosexual orientation (indicative of greater short-term mating orientation) were more likely to use direct competition tactics than were more restricted men. Restricted men instead highlighted their positive personal qualities. Men's intrasexual rivalry is also subject to differences in the overarching mating system. Male-male competition is most common in polygynous mating systems, where males are more likely to compete over gaining and maintaining mating access to females (female defense polygyny) or reproductively relevant resources (resource defense polygyny). For instance, in polygynous societies, where some men are able to monopolize significant reproductive opportunities and exclude others, the likelihood of civil war (i.e., male coalitional aggression) increases (Kanzawa 2009).

Another contextual factor influencing men's (and women's) intrasexual rivalry is the ratio of reproductively viable men to women within a given population, otherwise known as the operational sex ratio. Recent experimental evidence has shown that when men and women are primed to perceive that mates are scarce, they report a more intrasexually competitive attitude and express more jealousy and willingness to aggress indirectly against a hypothetical mate-poacher trying to steal their partner, with men also reporting a

modest increase in willingness to aggress physically, relative to those participants primed with mate abundance (Arnocky et al. 2014b). Barber (2009), using murder data from the United Nations and homicides from World Health Organization, showed that killings in both data sets increased alongside a female-biased sex ratio (i.e., a larger proportion of females to males). This finding held independent of statistical control for economic development, income inequality, urbanization, population density, the number of police, and whether the country was a major center of illegal drug trafficking.

Men's relative mate-value and social standing has also been linked to their intrasexually competitive behaviors. Poor and single men are more likely to commit homicide relative to men who are married and well-off (Wilson and Daly 1985). Yet some research has shown that self-perceived mate-value (SPMV) positively predicted young Indian men's use of aggression (Archer and Thanzami 2009); with SPMV previously being linked also to willingness to inflict discomfort upon another person (i.e., using the "hot sauce" paradigm) and trait measures of aggression (see Archer and Thanzami 2009 for review). The apparent disconnect between perceived mate-value and discrepant information about actual mate-value may thus be a particularly potent predictor of aggression. In two studies, Bird et al. (2016) showed that narcissistic (high perceived value) men who received information suggesting they were of low objective mate-value in a mock online dating paradigm engaged in more retaliatory aggression toward a same-sex rival in a point subtraction aggression task relative to men who were not narcissistic and received low mate-value scores or men who received high mate-value scores.

Lastly, the efficacy of men's phenotypic markers of dominance and masculinity as well the efficacy of behavioral aggression in being selected for by females may vary as a function of their fluctuating mate-preferences across the ovulatory cycle. Giebel et al. (2013) exposed women to one of four descriptions of a soldier's experience after returning from war, which included trauma related symptoms with (1) high or (2) low appetitive aggression, or no trauma related

symptoms with (3) high or (4) low appetitive aggression. Participants rated the man on desirability as a short term or long-term sex partner. Results showed that women preferred a soldier high in appetitive aggression as a short-term mate but not as a long-term partner, and this effect was stronger for women in their fertile phase of the menstrual cycle. Similarly, Gangestad et al. (2004) showed that when viewing tapes of men competing for a potential lunch date, women who were in the fertile phase of the menstrual cycle were more likely to rate men who displayed social presence and direct intrasexual competitiveness as more desirable short-term, but not long-term, partners. Taken together, these results suggest that women's preferences for aggressive men are higher during fertile windows, especially within the context of short-term mating.

Conclusion

Adaptations for increased intrasexual rivalry among men have been observed in sexually dimorphic human physiology, mating psychology, and related behaviors. Men's intrasexually competitive tactics range from resource displays, to derogation of rivals, to direct aggression, warfare, and homicide. Male rivalry results from intersexual and intrasexual selection, whereby sex differences in obligatory parental investment, reproductive potential, and variability compel the evolution of male rivalry for valuable reproductive resources and opportunities. Contextual factors, including mating systems and individual mating goals, the number of mates available locally, and men's relative mate-value, as well as ovulatory shifts in women's mate preferences, can influence the content and intensity of men's intrasexual rivalry.

Intrasexual Rivalry Among Women

Steven Arnocky
Department of Psychology, Faculty of Arts and Sciences, Nipissing University, North Bay, ON, Canada

Synonyms

[Intrasexual competition](#); [Intrasexual selection](#); [Within-sex competition](#); [Within-sex selection](#)

Definition

Intrasexual rivalry is a driving force behind sexual selection. Women's intrasexual rivalry surrounds competition over reproductive opportunities and resources.

Introduction

Humans are among the less than 5 % of mammals that engage in biparental care. Men who invest resources toward mates and offspring are compelled to be more selective in their mate choice. Because men vary widely in their investment and in their overall value as a mate, women can benefit their reproductive fitness by outcompeting intrasexual rivals for the best mates. Yet because women must also remain alive to rear offspring, adaptations for same-sex rivalry are characteristically different in many ways from male competitive adaptations. Women are less likely to rely on violent and physically risky strategies. More surreptitious forms of competition by means of verbal derogation and indirect aggression are considered as evolved mechanisms for defeating same-sex rivals. Competition among women varies depending upon contextual factors such as mating systems and the number of mates available in the environment.

In terrestrial mammals, including humans, sex differences in obligatory parental investment are a strong predictor of sexually dimorphic phenotypes associated with intrasexual rivalry. In the vast majority of species, female parental investment is much greater than that of males, conferring males with increased yet more variable reproductive potential and females with a heightened impetus to be more selective with whom they mate. From this perspective, females benefit primarily from selecting among the most desirable and competitively efficacious males, given that their reproductive output (in terms of number of offspring produced) will remain relatively stable, whereas males who are best adapted to attract or otherwise obtain females and/or to defeat same-sex rivals for mating opportunities or relevant resources will pass on their genes with much

greater frequency than those males who are less-well-suited to these tasks. Over generations, males take on the competitively adaptive heritable characteristics of their ancestors, which can include larger physical stature or weaponry for fighting as well as a more aggressive psychological and behavioral disposition that is beneficial for quelling rival males. From this perspective, it has traditionally been assumed that intrasexual rivalry among females does not exist, or if it does, matters only to an extent that pales in comparison to what is seen among males. However, recent reformulated models of sexual selection have countered this view by considering intrasexual competition as centering upon more than mere access to mating opportunities but rather upon competition over any mating-relevant resources (Rosvall 2011). From this perspective, research has shown that female intrasexual rivalry (1) exists in many diverse species and (2) has evolved to solve a wide variety of mating-relevant adaptive problems, including accessing food, nesting sites, social status, and, in species characterized by biparental care, male investment. Rosvall (2011) noted that although females sometimes compete for number of mates, more often they compete for male provisioning of direct or indirect (i.e., genetic) benefits. Ultimately, intrasexual competition among females for such resources can have a meaningful impact upon reproductive success. In some primates, for instance, high ranking females produce more surviving offspring and daughters that reach sexual maturity earlier, whereas females who fall victim to intrasexual harassment can suffer dire consequences, such as spontaneous abortion of pregnancies in some primates (see Arnocky and Vaillancourt 2014; Rosvall 2011 for review).

Humans offer a unique model for the study of female intrasexual rivalry, given that we are among a minority of less than 5 % of mammalian species in which both sexes invest resources and parental care toward their offspring. Men's provisioning of parental care may offset the costs of monogamy by increasing the survival rate of offspring, and might also provide repeated sexual access to a partner, or deter against a partner's extra-pair copulations (see Arnocky and

Vaillancourt 2014). Because men also invest considerable resources toward partners and offspring, they too are highly discriminating in their long-term mate choice (see Arnocky and Vaillancourt 2014). Moreover, not all men are equally desirable to women as long-term mates (whereby men's ability to provide direct-benefits varies) or short-term mates (whereby men's ability to provide indirect/genetic-benefits varies). Differential mate-value among men equates to there being a limited supply of desirable men, for which women must compete. This competition is characterized by two interrelated phenomena: *intersexual selection*, which refers to the nonrandom choice of mating partners between the sexes (applied to sexual selection among women, this often entails the desire to alter one's physical appearances to appear more desirable to men), and *intrasexual selection*, which refers to the direct rivalry between members of one sex for reproductive resources or access to members of the other sex.

Sex Differences in Physically Violent Competition

Women's direct intrasexual competition is characteristically different from that of men. From a fitness standpoint, women have more to lose, relative to men, from engaging in risky physical altercations characteristic of male intrasexual rivalry. Even though humans are considered a biparental species, women still provide most of the *obligatory* parental care required for offspring survival. Whereas ancestral men's inclusive fitness relied upon obtaining reproductive opportunities, women's relied more on their ability to rear offspring through early life stages (Campbell 2013). A mother's death is considerably more debilitating to a child's survival relative to a father's death (Sear et al. 2000). The costs associated with direct aggression and other risky forms of competition are therefore greater for women than for men, and women's intrasexual competition necessitates greater risk aversion (see Arnocky and Vaillancourt 2014; Campbell 2013 for review).

The greater cost associated with women's use of physically risky competition strategies is well exemplified by studies of sex differences in

human physiology and aggression. First, although humans are much less sexually dimorphic in terms of their physical size (males are approximately 15 % larger than females) relative to some early hominin species, such as *Paranthropus robustus*, and other closely related primates (e.g., Lockwood et al. 2007), it is nevertheless evident that “sexual dimorphism and violent male-male competition are ancient and enduring elements of our human evolutionary history” (Daly and Wilson 1988, p. 143). These elements of our evolutionary past are readily observable in the sex-differentiated aggressive behaviors of contemporary hunter-gatherer and industrialized societies. Cross-culturally, women less often exhibit extreme forms of overt physical aggression, including interpersonal violence, homicide, and warfare, relative to men (e.g., Daly and Wilson 1988). These sex differences are evident from a very early age and may be mediated, in part, by differences in fear responses related to aggression, such that females are more likely to express fear within the context of physical danger. In support of this, a meta-analytic review of sex differences in aggression by Eagly and Steffen (1986) found that sex differences in aggression were larger when women perceived that their aggression would pose a danger to themselves. It is important to note here that women’s lesser involvement in direct physical aggression does not mean that they do not engage in such behaviors or that women’s physical aggression is somehow unrelated to intrasexual rivalry in the same manner as men’s aggression. Burbank (1987) conducted a cross-cultural survey of women’s aggression, which ranged between verbal and physical violence, and noted that such behaviors were (1) common (physical aggression by women was observed in 61 % of the cultures analyzed) and (2) most often directed at other women within the context of competition for mates or reproductively relevant resources (e.g., subsistence products). Reasons underlying young girls’ and adolescents’ reports of physical aggression also include fighting over access to boys as well as reputational defense, status enhancement, and avoidance of victimization (see Campbell 2013). However, in circumstances of girls’ and women’s intrasexual

competition, physical aggression remains a much rarer exception relative to more common tactics of verbal derogation and indirect (social) aggression. Next, I describe women’s use of verbal derogation and indirect aggression situated within the context of competition over reproductively relevant resources such as status and mates, as well as describe why these acts of aggression often focus on physical appearance and sexual reputation, and whether there are tangible mating-relevant outcomes for perpetrators and victims.

Verbal Derogation of Attractiveness, Promiscuity, and Other Components of Mate-Value

Verbal derogation refers to negative statements that are made toward other individuals. Verbal derogation is a tactic used by both men and women in intrasexual rivalry. However, rival derogation often differs between the sexes in terms of content, such that same-sex rivals tend to derogate facets of others that are crucial to mate-value or desirability to the opposite sex. For instance, Buss and Dedden (1990) showed that women, more than men, reported derogating the physical attractiveness of a rival, calling a competitor promiscuous, and suggesting that other women fail to provide reproductive value through intercourse (i.e., calling other women a “tease”). Similarly, Campbell (2013) noted continuity in the epithets which frequently appear in recounts of girls’ fights with other girls, which include verbal barbs such as “slag,” “slut,” “whore (ho),” “tart,” “ugly,” and “fat.” Targeting these aspects of a girl’s or woman’s mate-value directly counters boy’s/men’s preference for mates who best display various physical cues to health and fertility, such as feminine and symmetrical facial features, a low waist-to-hip ratio, clear skin, and lustrous hair (see Arnocky et al. 2014a for review), as well as mates who are sexually accessible (especially in short-term mating where conservative or low sex-drive women may be disfavored), yet who are simultaneously faithful (especially in long-term mating) in order to counter paternity uncertainty (Buss and Schmitt 1993).

Individual differences in the use of such derogation strategies exist, with women who express a

more unrestricted sociosexuality being more likely to disparage other women. For example, Bleske-Rechek and Buss (2006) found that an unrestricted sociosexual strategy among both men and women was associated with more frequent use of dominance displays, derogating a rival's physical appearance and popularity, and attempting to dominate competitors. The sexuality of the *target* might also influence the extent to which women are derogated by other women. Grabe et al. (2012) exposed women to clips of a news anchor who was either more sexualized (wearing a dark jacket and skirt that accented her waist-to-hip ratio, bright red lipstick, and a necklace) or less sexualized (wearing a shapeless dark blue jacket and skirt that deemphasized her waistline and no lip color or jewelry). The researchers found that women who were exposed to a sexualized woman news anchor derogated her appearance efforts ("... her lipstick was too red, it was distracting" or her "outfit was terrible for her body"), her agreeableness ("self-centered"), contentiousness ("she stood awkwardly"), emotional stability ("tense and fidgety"), and intelligence ("stupid" and "dumb") more than women exposed to a less sexualized woman news anchor.

Similarly, Vaillancourt and Sharma (2011) showed that almost all women who were randomly exposed to an attractive female confederate (dressed provocatively) engaged in more derogatory behavior toward her relative to when she was dressed in more conservative clothing. Example statements given by the authors included women implying to another participant that the confederate was dressed as if she wanted to have sex with one of her professors or that her "boobs were about to pop out." One participant was reported to have looked the confederate up and down and to have said "what the fuck is that?" while exhibiting a disgust reaction. Moreover, women were less likely to want to introduce their boyfriends to the confederate, to have their boyfriends to spend time with the confederate, or to become friends with the confederate, when she was provocatively versus conservatively dressed.

Ultimately, verbal derogation can have an important and reproductively relevant influence

upon the target. Fisher and Cox (2009) showed that relative to men's initial attractiveness ratings of women's faces, receiving subsequent negative derogatory statements about those faces from a woman who they viewed as attractive significantly reduced their perceptions of the target woman's attractiveness. Derogatory statements made by attractive women were much more impactful than derogatory statements made by an unattractive woman. However, direct verbal derogation tactics can also be damaging to the perpetrator. Fisher and colleagues (2010) examined men's and women's perceptions of women who were purported to have made a derogatory statement about another woman's appearance, personality, or sexuality. Their results showed that men significantly decreased their evaluations of the derogator's friendliness, kindness, trustworthiness, and overall desirability as a mate, relative to when their photos were presented without having made a derogatory comment. Women also rated derogators more negatively along the same dimensions and also decreased their views of the derogator's fitness as a parent and her physical attractiveness, and in the case of appearance derogations, her promiscuity, relative to when the photos were presented as not having made derogatory comments.

Together, these findings suggest that making direct derogatory comments about intrasexual rivals, such as "She's pretty but... She wears a lot of makeup and wears padded, pushup bras all the time (even to the gym!)..." or "I know her really well. She's a virgin and is holding out until she's married..." (Fisher et al. 2010, p. 269) can have negative effects upon the target but also upon the perpetrator's attractiveness to men and appeal as a same-sex ally. This body of research suggests that while verbal derogation is an effective strategy for disparaging rivals, it is also risky, and thus women may sometimes rely on more surreptitious acts of aggression meant to damage same-sex rivals.

Indirect (Also "Social" and "Relational") Aggression

Beyond the study of direct verbal derogation tactics, researchers have also examined a

related but conceptually distinct phenomenon termed indirect aggression (otherwise termed “social” or “relational” aggression; although see Ingram 2014 for some conceptual differences between constructs). Research has shown that women are much more likely to use indirect aggression relative to physical aggression, which involves purposefully and often covertly manipulating interpersonal relationships through acts of social exclusion, veiled criticism, breaking confidences, gossip, and rumor spreading in order to harm others, which relative to physical violence confers a lower likelihood of retaliation, physical, social, or legal consequence (see Arnocky and Vaillancourt 2014 for review). Studies of sex differences in indirect aggression have shown that women are often equally or more likely than men to use indirect aggressive tactics (see Hess and Hagen 2006). Recent evidence suggests that women, more than men, preferentially remember gossip about a potential rival’s physical attractiveness rather than their wealth (De Backer et al. 2007). Beyond a focus on physical attractiveness, women’s indirect aggression is also intimately tied to sexuality reputation. Leenaars et al. (2008) showed that among older adolescents, recent sexual behavior correlated with increased risk for indirect victimization, suggesting that indirect aggression might also be used to regulate sexuality among the peer group (see Vaillancourt 2013). Indirect aggression seems to be motivated by mating and status goals. Griskevicius and colleagues (2009) primed men and women with status and courtship motives and subsequently assessed willingness to aggress directly and indirectly against a same-sex rival. For women, results showed that both status and courtship motives increased willingness to engage in indirect aggression (e.g., socially excluding a rival). Moreover, when women were primed with competition over scarce resources, they became more willing to aggress directly against a same-sex rival.

The use of indirect aggression is functional as a competitive tactic for at least three interrelated reasons: First, it is damaging to targets and has

been shown to promote depression, lower self-esteem, school drop-out, and even suicide among victims (see Vaillancourt 2013 for review). Second, indirect aggression has been linked to increased status (in terms of popularity and dominance, although not likeability or preference) within the social hierarchy (see Ingram 2014 for review). Third, indirect aggression has been related to mating success and victimization with decreased mating success. For example, in a longitudinal study of adolescents, Arnocky and Vaillancourt (2012) explored whether various types of peer-aggression confer mating benefits to perpetrators. Results showed that peer-rated indirect aggression, but not physical aggression, predicted having a dating partner 1 year later, controlling for age, initial dating status, popularity, and physical attractiveness, whereas being a self-reported target of bullying negatively predicted having a dating partner at 1-year follow-up. Similarly, White et al. (2010) showed that women who reported more indirect aggression toward peers had earlier ages at first sexual intercourse, whereas women who were more victimized in adolescence experienced later ages at first sexual intercourse.

Arnocky et al. (2012) explored how individual differences in self-perceived mate-value (in this case, physical attractiveness compared to same-sex rivals) related to use of indirect aggression in a large sample of heterosexual women who were in dating relationships at the time. Results showed that women who believed they were of lower physical attractiveness relative to other women were more likely to perpetrate indirect aggression against peers. Moreover, women who perceived themselves as being more physically attractive than other women were more likely to also report being indirectly victimized by other women with greater frequency. Similarly, Leenaars et al. (2008) found that among adolescents, attractive females were at greater risk for indirect victimization. This makes sense in light of the fact that physically attractive women report greater success in stealing other women’s romantic partners (Sunderani et al. 2013). Together, these findings suggest that women may

preferentially target attractive women for indirect aggression.

Ovulatory Shifts in Women's Intrasexual Competition

Females' intrasexual rivalry has been shown to intensify in relation to ovulatory shifts. Fisher (2004) examined whether women's evaluation of other women's attractiveness differed during ovulation (i.e., maximum fertility) versus during menstruation (i.e., minimal fertility). Results showed that maximally fertile women rated other women's facial photos as being less attractive compared to menstruating women, ostensibly due to increased intrasexual competitiveness during the time when reproduction is most likely. Intrasexual competition during the follicular phase of the reproductive cycle has been shown to be related to hormonal functioning. Moreover, among normally ovulating women, increased conception risk is associated with women's greater dehumanization of other women (but not of men or of elderly women) and greater intrasexual competitiveness (Piccoli et al. 2013). Cashdan (2003) had female participants complete diary entries detailing competitive interactions and noted whether or not aggressive tactics were implemented. The researcher also obtained measures of total testosterone, free testosterone, androstenedione, estradiol, and cortisol in the follicular phase of the menstrual cycle. Results showed that women high in androstenedione (an androgenic steroid produced by the adrenals) were more likely than other women to express their competitive feelings through verbal aggression, whereas women with low androstenedione and total testosterone were less likely to express their competitive feelings overtly. Some research suggests that use of hormonal contraceptives lowers intrasexual competition among some women. Cobey et al. (2013) found that among pair-bonded (but not single) women, endorsement of a self-report scale for intrasexual competition declined during use of hormonal contraceptives relative to when they were regularly cycling at a fertile and a nonfertile cycle stage, even after controlling for age, relationship length, and satisfaction.

Influence of Mate Scarcity on Women's Intrasexual Rivalry

Because competitor derogation, direct, and indirect aggression all require energies that might otherwise be spent on addressing other adaptive problems and because each of these tactics pose varying levels of risk, women would be expected to generally avoid their indiscriminate use but rather to rely upon environmental cues to their necessity. One such environmental cue which might motivate greater use of competitor derogation and intrasexual aggression is the operational sex ratio – or the ratio of reproductively capable males to females in a given population. When potential mates are scarce relative to intrasexual rivals, women may be compelled to compete more vigorously for rarer mating resources and opportunities. In support of this, Arnocky et al. (2014b) primed participants with perceptions of either mate scarcity or abundance using bogus magazine articles and subsequently had them complete measures of intrasexual competitiveness as well as jealousy, direct, and indirect aggression toward a hypothetical mate-poacher. Results showed that women (and men) were more intrasexually competitive, more jealous, and more willing to use indirect aggression against a same-sex rival after being primed with mate scarcity.

Conclusion

Women can benefit in multiple ways from successful intrasexual competition, including in securing and maintaining mating opportunities and social status (see Arnocky and Vaillancourt 2012), and this is consistent with recent studies of other species highlighting the importance of competition among females to reproductive success (see Rosvall 2011 for review). Given differential challenges faced by women relative to men, such as the need to remain alive in order to rear offspring, women's intrasexual rivalry is characteristically different from that of men. Women are less likely to perpetrate physical violence against other women. Women's intrasexually competitive tactics range from verbal derogation of rivals (often in reference to mate-value characteristics such as

physical attractiveness and sexuality) to indirect aggression involving more discrete social manipulations, gossip, and exclusion. Use of these tactics can be effective in harming rivals and in facilitating mating success but also entail risks such as lower desirability to males or reduced likeability. Accordingly, the use of these tactics is not indiscriminate but rather is more likely under contextual pressures including during phases of the ovulatory cycle in which conception is most likely or when mating opportunities are perceived to be scarce.

[Intrasexual competition](#); [Sexual selection](#)

Definition

Intrasexual selection can refer to the act of competing with members of one's own sex (for status, tangible resources, or directly for access to mates) as well as the evolutionary process that shapes the traits employed in this competition.

Introduction

In November of 2016, a striking image began making its way around the internet, two Alaskan bull moose, with their antlers locked, drowned, and frozen together at the presumptive site of their final combat – a stark illustration of the risks that animals will endure, or even pursue, in response to intrasexual selection pressures. Intrasexual selection refers to the within-sex component of the broader process of *sexual selection* (Darwin 1871). Whereas the other half, intersexual selection, is characterized by the choice of mates by the opposite sex, intrasexual selection refers to competition with members of the same sex. Among humans, the particular nature of the competition varies by sex and culture, but same-sex competition is motivated by the more fundamental evolved goal of securing a viable mate or mates.

Competition for Mates, Available and Otherwise

The competition for mates includes those who may already be “spoken for” – thereby often

precipitating the jealousy of the existing partner. And there is a rich literature on the evolutionary psychology of sexual/romantic jealousy. That men are more upset than women about their partners' sexual infidelity (actual, suspected, or merely hypothetical) and women more than men upset by emotional infidelity (i.e., development of romantic attachment to another rather than sexual activity per se) is a remarkably consistent finding across cultures (e.g., Brase et al. 2004; Buss et al. 1999; Fernandez et al. 2006; Whitty and Quigley 2008). This is consistent with the evolutionary perspective of jealousy as an evolved response to the adaptive problems of cuckoldry (exclusively for males) and loss of partner's resource investment (primarily for females), both of which emerge as effects of successful intrasexual competition from one's rivals.

Males and females alike may resort to aggression as a way of warding off or retaliating against their intrasexual rivals, but once again there is a key sex difference; the apparent equivalence is the consequence of too broad a definition for aggression. Male-typical (or "covert") aggression entails physical violence, whereas female-typical ("relational" or "overt") aggression relies upon verbal barbs and inflicting reputational damage on one's rivals, without the use or even the threat of violence (Hyde 1984; Werner and Crick 1999). The novelist Margaret Atwood memorably alludes to the latter in her book *Cat's Eye*: "Little girls are cute and small only to adults. To one another they are not cute. They are life sized (Atwood 1989, p. 124)."

Female-Female Competition

Fisher (2013) elaborates with a catalog of specific behaviors characteristic of this sort of aggression, including "breaking confidences; criticizing others' clothing, appearance, or personality;... excluding from the group; writing nasty notes; and spreading false stories and gossip." Indeed, and presumed to function for effectively tracking and engaging in gossip, women are superior to men in recalling details about same-sex rivals (De Backer et al. 2007). Such aggression, though

of a different species from throwing a punch at a rival's face, nonetheless appears to be employed in service of the same goal – intrasexual competition for desirable mates. Buss and Dedden (1990) studied the nature of insults in the context of intrasexual competition and found that women's derogation of their rivals focused on characteristics shown in previous cross-cultural research (Buss 1989) to be important components of their mate value. In other words, it appears that the function of competitor derogation is not simply to demean or hurt the feelings of one's rival as a benefit in its own right but to reduce her chances of being chosen as a mate – which, it should be noted, would also boost one's own chances of being selected.

There are, however, alternate means of competition. In addition to relational aggression (derogation or manipulation of competitors), competition may also take the form of mate manipulation or of self-promotion. The last of these is, based on self-report at least, the type most frequently employed by women (Fisher and Cox 2010). One likely reason is that men are romantically interested in women who, in addition to possessing high physical attractiveness, are perceived as kind and gentle – an impression difficult to convey while attacking one's rivals. Women exhibit increased interpersonal warmth and (perhaps ironically) decreased dominance at mid-cycle, when they are most intrasexually competitive (Markey and Markey 2011). When women have been shown a series of images of beautiful women, they show an increased desire to enhance their own attractiveness, not only through innocuous means such as cosmetics and clothing choices but also through higher risk strategies such as taking diet pills (Hill and Durante 2011).

Male-Male Competition

Sexual selection is attested to in many animal species, including our own, in the form of sexual dimorphism. Natural selection in the traditional sense of selection for traits contributing to an organism's survival should, with few exceptions

(pelvic bones to accommodate childbirth in females, the sex organs themselves, milk glands in female mammals), result in matching phenotypes across sexes. Absent the effects of sexual selection, dimorphism would not be predicted for such characteristics as height, upper body strength, and craniofacial morphology. To the extent that we observe sex differences in such characteristics, we are witnessing the handiwork of intrasexual and intersexual selection. Human males, irrespective of time spent at the gym, divert valuable resources to the growth and maintenance of powerful muscles in the arms and torso, a product of the selection pressure of intrasexual combat. It may not be possible to quantify the contributions from the selection pressures of hunting, fighting, and sexual signaling with great precision, but we know from cross-species comparisons that the contribution from fighting alone can be sufficient to drive a process of *run-away selection* (Fisher 1915) for extreme sexual dimorphism in size and strength.

The walrus is a good illustration of a key principle here, that the intensity of intrasexual selection is proportionate to the magnitude of the available reward. To take the example of the Pacific walrus, adult males are 45% larger than females, a difference entirely attributable to mating competition (Fay 1982). The losers in these competitions are commonly maimed, occasionally killed in combat (or die from their injuries later in the season), and even the victors acquire such injuries that they can rarely maintain their dominant position for more than a couple of breeding seasons. However, as the females prefer to mate exclusively with the most successful fighter in the population, there is (genetically speaking) no incentive for a male to shirk the fight. That nearly all the males then are likely to lose does not dissuade them from attempting to do otherwise. The male-male competition within our own species is generally tame by comparison, albeit more frequently violent than that observed among women.

Gangestad et al. (2004) recorded videos of men who were told that a woman would be viewing the videos and choosing to go on a date with either him or another (unknown) male participant. Each

of these men was instructed to use the video to explain why the woman should choose him. Those who were more intrasexually competitive in their videos, via both self-promotion and derogation of the unknown rival's presumed inferiority, were rated as more attractive by female participants on high fertility days of their ovulatory cycle than by those on low fertility days, specifically in the context of short-term mating. This combination of cycle effect and context effect is characteristic of females' evaluations of males' signals of high genetic quality (see Gangestad et al. 2005).

Sperm Competition

The preponderance of long-term monogamous pair-bonds and rarity of large harems in humans makes such heightened intrasexual competition less common in our own species. We are notably lacking in tusks, for example. However, several convergent lines of evidence (testicular volume relative to body mass, observed rates of extrapair paternity, preference for "polyandrous" pornography) indicate that sperm competition has been a recurrent feature in the human environment of evolutionary adaptedness (EEA). That is, the female reproductive tract acts as a secondary battlefield for intrasexual competition whenever two or more men have been chosen as mates by the same partner (during the overlapping lifespans of the men's ejaculated sperm).

Other things being equal, producing and ejaculating larger numbers of sperm increase a male animal's chance of reproducing. However, the point at which it becomes more valuable to divert one's limited energy into the production or maintenance of muscle tissue, vital organs, bones, etc., rather than producing still more sperm, varies as a function of the chance of sperm competition. Simply put, those species in which the sperm of two or more males never simultaneously occupied one female's reproductive tract have never faced the adaptive challenge of sperm competition and would therefore show no evidence of having evolved in response to sperm competition. Consequently, one can infer the relative degree of

sperm competition in cross-species comparisons of the testicular mass/total body mass ratio.

Short (1979) performs this comparison for great apes, including *Homo sapiens*. The testis/body ratio for humans is intermediate between those for chimpanzees and gorillas, consistent with the different mating dynamics across the species. Chimpanzees mate promiscuously. Gorilla females mate with a single dominant male, though he may have numerous mates. Human females vary within that range, with individual differences in *sociosexuality* (Gangestad and Simpson 1990) as well as temporary circumstances contributing variation to the choice to remain monogamous or not. The position of human males on the aforementioned spectrum of testicular size indicates that this state (frequent but not exclusive monogamy) prevailed in ancestral human environments as well.

Perhaps the strongest evidence of human sperm competition is genetic evidence of extra-pair paternity. The genetic evidence indicates considerable variability in the frequency of human cuckoldry across cultures. At the lower end, Sasse et al. (1994) discovered an extra-pair paternity rate just shy of 1% in a Swiss sample. A subsequent study, using a Mexican sample, revealed that the ostensible father was in fact a cuckold in 11% of cases (Cerdeña-Flores et al. 1999). In any case, given the typical investment contributed by a father over the child's lifespan, mistaken paternity in even one case out of 1000 would provide strong selection pressure for (a) detection and prevention of partners' sexual infidelity, (b) sperm competition, and (c) detection of extra-pair paternity *ex post facto*.

Further evidence comes from investigation of the effects of pornography. That it is intended to create sexual arousal in the consumer is true more or less by definition. However, not all porn is equally successful in this endeavor. Heterosexual males are sexually aroused by (and subjectively enjoy) pornography, provided that it depicts at least one woman. It may depict more than one woman, and it may depict one or more men, or no men at all, and the men will find it arousing regardless. However, the depiction of a woman having

sex with multiple males is more arousing than the other combinations, as attested to by which pornographic videos are most likely to be purchased, as a function of the images used to advertise them (McKibbin et al. 2013).

An experiment by Kilgallon and Simmons (2005) revealed that men ejaculate sperm of greater motility after viewing videos depicting polyandrous sex (i.e., multiple men copulating with a single woman) compared to videos depicting lesbian sex. This is remarkable enough to bear some repeating. While pornography in general is sexually arousing by design, the experiment reveals that men's evolved adaptations for sexual arousal and sperm competition are precisely calibrated to such a degree as to respond differentially to varying levels of sperm competition cues – and that these have an impact not merely at the level of conscious preferences or subjective judgments of arousal but on the more literal output of the sperm themselves, the body's "decision" of which spermatozoa to force through the urethra and which to retain in the epididymides during a particular ejaculation.

Pornography represents a sort of supernormal stimulus, but the ejaculate data similarly testify (so to speak) to our evolutionary history of sperm competition in more ecologically authentic circumstances as well. Men's ejaculated sperm count when having sex with their regular partner varies in direct proportion to the amount of time they have spent apart since they last had intercourse, even after controlling for the total amount of time elapsed since the previous ejaculation (Baker and Bellis 1995).

A Note on Homicide

The most impactful form that intrasexual competition may take is homicide. There is disagreement within the evolutionary community on the question of whether humans possess an evolved adaptation for homicide (Duntley and Buss 2005) or if it merely arises as a by-product of other adaptations (Daly and Wilson 1988). In either case, the phenomenon of murder and the underlying psychology of homicidal ideation are instructive on the

broader question of intrasexual selection. A majority of both men and women report that they have at least once thought about (literally) murdering someone (Kenrick and Sheets 1993). The most common category of victim in these thoughts is an intrasexual rival, and some data suggest that *a majority of men would commit murder*, if guaranteed they could get away with it, in response to being cuckolded, humiliated, beaten up, or robbed by a rival (Buss and Duntley 1998). In the same study, some of the female participants (but none of the males) endorsed rival's physical attractiveness as a reason to commit homicide.

Conclusion

Reproductive success relative to one's conspecifics is the primary metric by which evolution judges an organism's success. Attractiveness perception, sexual arousal, and other evolved adaptations that are directly involved in mating operate in a context of intrasexual selection. In female-female competition and male-male competition alike, the competitive processes of intrasexual selection afford opportunities to increase the quality and quantity of one's potential mates. Sperm competition carries the intrasexual selection process farther still into mating territory. And ultimately, like the antlers of the two bull moose in their watery grave, it may not be feasible to truly disentangle the selection pressures of intrasexual selection from those of intersexual selection.

Intrasexual Violence and Aggression

Tara-Lyn Camilleri-Carter

Monash University, Melbourne, VIC, Australia

Synonyms

Contest competition; Intrasexual selection; Mate competition; Same sex aggression

Definition

Intrasexual violence is the intentional use of physical force to inflict harm on another, and it occurs between members of the same sex, in relation to competition over mates. Intrasexual aggression occurs between members of the same sex during competition for mates and is an intentional act to inflict harm on another. It can encompass direct and indirect acts. Aggression can have violent consequences – but not always – for example, gossip, ostracization, and scarification can intimidate without inflicting bodily harm to another.

Introduction

This entry provides a concise overview of the theory and evidence regarding intrasexual selection as a driving force – shaping patterns of human aggression and violence. It tends not to dwell on human violence and aggression as being purely unique behaviors that have unique underpinnings. Rather, it attempts to discuss an ultimate framework for the evolution of human aggression and

Intra-sexual Signaling

► Steve Gangestad

violence by putting humans into context equal with research on many taxa. While there are always within-taxa specificities, this entry attempts to find generalities. The evolution of sex roles, mating systems, and sex ratios are discussed as they relate to the distribution of human violence and aggression. As a necessity, this entry focuses on male intrasexual violence and aggression, simply because it is more prevalent among males, but does also consider intrasexual aggression and violence in women.

Male Intrasexual Violence and Aggression

Sexual selection is an evolutionary process that favors traits that lead to greater success in securing a mate and therefore greater reproductive success (Andersson 1994). It was Darwin (1871) who first referred to sexual selection whereby members of the same sex compete with each other for mates, as intrasexual selection. In vertebrates, males are typically more aggressive than females. Contest competition, when males of many taxa physically compete with each other for access to mates, has led to the evolution of a plethora of armaments – from pincers to antlers to fangs – that males use in battle with one another (Emlen 2008; Puts 2010). Although there are some exceptions, intrasexually selected armaments are rare in females (Berglund 2013). This evolved weaponry suggests that males are typically engaging in aggression during competition for mates more than females. Additionally, with females providing a greater amount of parental investment, a trade-off between parental investment and competing for mates typically exists. Fish are an exception to this because the trade-off is usually weaker or absent altogether (Jennions and Kokko 2010). Some bird taxa are another exception where the bias towards female parental investment is reduced comparative to mammals and reptiles (Goymann et al. 2015).

In humans, studies and crime statistics consistently show that violence and aggression are more prevalent among men than women. There are two caveats to this point: Adolescent girls use indirect aggression more than adolescent boys do

(discussed in more detail when considering female intrasexual aggression) and women use violence in romantic partnerships as often as men do (Cross and Campbell 2011). Sexual dimorphism in aggression begins in childhood from the age of two years onwards (Campbell 1999) and peaks in young adulthood (Archer 2009). Violent crimes are much higher among men, and male on male violent crime is the most prevalent (Campbell et al. 1998). This has led researchers to the hypothesis that differences in human same-sex violence and aggression are part of a greater evolutionary pattern, which is driven by the different strategies that males and females employ to secure mates (Darwin 1871).

Underpinning this sexual dimorphism in violence are differences in potential reproductive outputs for men and women, conventional views state that men are usually capable of siring many more offspring than are women (Archer 2009). Trivers (1972) reasoned that males compete more for reproductive opportunities because they do not extend as much effort towards parental investment in offspring. Bateman (1948) showed in *Drosophila* that females expend more energy in gamete production, than do males in sperm production (anisogamy). It therefore would make it more beneficial for males to seek out multiple mating opportunities in situations where offspring require little parental investment, or where mothers invest a greater amount of energy into caring for their offspring, whereas when parental care is equal or greater in males the strength of intrasexual aggression in males is reduced. Furthermore, in so-called role reversed taxa, such as the polyandrous black coucals, males brood the eggs and care for the hatchlings, whereas the female birds compete and are the larger, more aggressive sex (Goymann et al. 2015).

Consideration of Sex Role Evolution

Considering sex role evolution is imperative to answering the question of whether intrasexual selection could have shaped human aggression and violence. Especially when we consider that

human males follow the same general pattern of being more aggressive and violent than their female counterparts and are often the sex that uses aggression and violence to compete for mating opportunities (Carter and Kushnick 2018). Kokko and Jennions (2008) argue that explaining sex roles is more nuanced than much of the past conventional literature considers. For example, the notion that males are able to produce more offspring than females violates the “Fisher Condition,” which states that males are inevitably limited by a female’s rate of reproduction. Despite this, in humans men on average still have a greater variance in number of offspring than women do (Cross and Campbell 2011). Secondly, the assumption that females (more than males, due largely to anisogamy) cannot afford to lose their past investments in offspring violates the “Sunk Costs” fallacy (also termed Concorde fallacy), a cognitive bias that describes the tendency to think that previous effort expended in an activity makes further effort in that activity more profitable. This argument also assumes that female’s effort in gamete production is linked to greater amounts of parental care later on.

Due to the work of Kokko and Jennions (2008) and others (for examples see: Goymann et al. 2015; Schacht et al. 2014), models that attempt to explain sex role evolution now take into account not only Operational Sex Ratio (OSR) or the ratio of males to females in a population that are of reproductive age, but also the availability of males and females. This highlights the need to consider Adult Sex Ratios (ASRs) and take into account the effect ASRs have on mate competition; this is discussed further in the next section. Other things to consider in sex role models are whether young born are altricial, i.e., underdeveloped at birth and requiring more care such (e.g., humans) or precocial, i.e., more developed and independent at birth (e.g., giraffes), as this will dictate the amount of parental care required. Additionally, mating system, paternity certainty, the strength of sexual selection, and even possible sexual conflict are all interrelated factors that need to be taken into account when attempting to explain sex role evolution (Kokko and Jennions 2008).

The social role theory proposes an alternative to sexual selection theory in explaining sex roles and their relationship to aggression. According to the revised social role theory, the differences in aggressive behavior exhibited by men and women are due to societal divisions of labor, rather than sexual selection (Eagly and Wood 2011). Although the proponents of the social role theory do allow that the social requirements of the sexes are interacting with ecological and environmental factors, they disagree that sexual selection can explain patterns of human aggression for two main reasons. Firstly, that explaining aggression using intrasexual selection relies mainly on the assumption of humans employing a polygynous mating system. Secondly, that sexual dimorphism is lower in humans comparative to other primates (Archer 2009). While most researchers do not deny that social and cultural norms play a role in explaining human violence and aggression, the evidence shows them unlikely to explain the entire pattern. Putting humans into evolutionary context with other taxa – it would be unparsimonious to assume human exceptionalism (Archer 2009).

Nevertheless, it is valuable to address the criticisms of the intrasexual selection explanation. Firstly, as this section addresses, explaining sex roles in all taxa is a complex interplay of factors, of which mating system is only one. Although serial monogamy is common in humans, evidence still shows that polygynous mating, or extra-marital couplings are commonplace and contribute to men having a larger variance in number of children than women (Cross and Campbell 2011). Secondly, it is accurate to say humans are generally less sexually dimorphic in say body size than our ancestors, although issues with gauging this are discussed in the next section. Nonetheless, it is not entirely accurate to say that humans are less sexually dimorphic compared to all primates, even if one only considers apes. For example, the family *Hylobatidae* (gibbons and siamangs) are monogamous (although sneaky mating does occur) and they are much less sexually dimorphic in both body and canine size than humans are – and are the only nonhuman primate to employ monogamy (Kramer and Russell 2015). The

relationship between mating system and intrasexual selection is discussed in the following section.

Mating System can Predict Strength of Intrasexual Selection

Phylogenetic studies show past ancestral mating system can often predict future mating strategies, and in turn mating system can affect the strength of intrasexual selection. A recent cross-cultural study showed that the intensity of intrasexual aggression is highest in societies that sanction polygyny and where the variance in number of wives is the greatest (Carter and Kushnick 2018). Although many of these societies practice serial monogamy more commonly (one partner at a time, or for a number of years), opportunistic polygynous mating is still occurring frequently, as it does even in societies where polygyny is outlawed (Cross and Campbell 2011; Kramer and Russell 2015). This opportunistic polygyny could be driving the intensity of male intrasexual violence and aggression. Granting modern humans are generally considered less sexually dimorphic in size than both the Australopithecines and early *Homo sapiens* fossils from the mid-Pleistocene (Kramer and Russell 2015).

Debate surrounds this point about variation between modern humans and/or hominid ancestors given sex determination and dimorphism are very difficult to gauge from the small sample sizes of fossils available, especially when these fossils do vary in size and are often fragmentary. It is also problematic to determine correlations between mating behavior and fossil size in extinct species (Plavcan 2012). Nevertheless, body size dimorphism in humans is commonly greater than in other monogamous species of apes (e.g., Gibbons), but smaller than in polygynous species (e.g., Gorillas) suggesting some degree of male antagonistic competition (Kramer and Russell 2015). Males (and females) can also compete for mates in aggressive yet nonviolent ways such as scarification for intimidation, which can act as an armament or an ornament. These nonviolent behaviors are unlikely to reduce the strength of

intrasexual competition but are likely to exhibit different selection pressures upon it (Carter and Kushnick 2018).

The Relationship between Sex Ratios and Violence

As touched on earlier, there is a relationship between sex ratios and violence that is mediated by mating behavior. As violence and aggression are usually more prevalent in men, a long commonly held belief is that an ASR skewed towards men will result in more violence. Additionally, due to females providing a greater parental investment, conventional sexual selection theory assumes this skews the OSR towards males. Schacht et al. (2014, pp. 214) termed this the “more men, more violence expectation.” This notion fits with long held views on sexual selection, such as the influential work of Emlen and Oring (1977) who coined the term OSR as a key measure of the potential intensity of sexual selection. The conventional view has been that male biased sex ratios lead to an increase in male-male competition. This explanation seems intuitive, and mathematically if one considers again that males are usually the victims and perpetrators of violent crime, more men additively equal more violent crime. This was the explanation given for the increasing violent crimes in China and India, due to a preference for sons – both countries had a male biased ASR (Oldenburg 1992; Dreze and Khera 2000; Edlund et al. 2007).

Although these notions appear intuitive, they have been challenged recently. Both mathematical and empirical evidence for such commonly held assumptions are not met (Kokko and Jennions 2008; Schacht et al. 2014; Carter and Kushnick 2018). In their review of data from 15 preindustrial societies, Schacht et al. (2014) demonstrated that there is more male-male competition when sex ratios are female biased. Further evidence for this comes from a recent cross-cultural study that found the strength of intrasexual selection was greater in female skewed sex ratios (Carter and Kushnick 2018). Kokko and Jennions (2008) have demonstrated that, under certain

circumstances, male biased adult sex ratios can lead to a decrease in competition. This is because some males will shy from competition when costs are high or probable benefits low – leading to an ASR that is a poor measure of OSR. That the strength of intrasexual competition among males may be higher when females are in excess does not necessarily negate the hypothesis that this could have shaped human male aggression, but it does illustrate a need for further evaluation of the relationship between human violence and mating.

To consider the relationship between human male violence and mating behavior, several points need to be taken into consideration. Firstly, competition for mates is not always violent; it can be aggressive without resulting in physical violence, such as intimidation tactics (Carter and Kushnick 2018). Male tactics depend on female mate choice, in situations where females prefer males who demonstrate their status, wealth, and resources nonviolently – nonviolent tactics will be the prevailing mode of competition. Crime statistics often do not delineate between intra- and intersexual violence and aggression, making gauging accurate relationships difficult. In a recent review of crime statistics worldwide and their relationship to male-skewed sex ratios, results were mixed and dependent on society, type of violence measured, and rate of violence (Schacht et al. 2014). For example, studies of India and China found positive relationships between male-skewed sex ratios and homicide rates, violent and property crime rates (Oldenburg 1992; Dreze and Khera 2000; Edlund et al. 2007). However, studies considering US cities found negative or mixed relationships between male-biased sex ratios and homicide rates (Messner and Sampson 1991). This is further evidence that there is no simple relationship between sex ratios and violent crime (Schacht et al. 2014).

Intrasexual Violence and Aggression in Women

Women consistently use violence less than men do, with the exception of violence within intimate

partner relationships (Campbell 1999). One possible reason for this disparity in intrasexual violence is that in humans it is the largely the female who expends energy towards enhancing their physical appearance. It is in this way females attract a mate and attempt to out-compete other females (Buss 2003). The trend toward monogamy or at least serial monogamy may have meant that men sought higher quality mates than under a polygynous mating system (Cross and Campbell 2011). Due to an expanding hominin brain, human babies became more altricial than previously seen in our ancestors; this meant human babies required more resources and energy to survive – this preceded the emergence of bi-parental care, monogamy, and co-operative breeding. Put simply, women required help to raise a child and therefore had to attract and compete as men do for mates – something that is quite rare in other species (Buss 2003; Cross and Campbell 2011).

While it is true that men's reproductive output will always be limited by female's reproductive capacity (Fisher's Condition), resulting in a reduction in males potential reproductive capacity – evidence still shows that men, even in modern society, have greater reproductive variance than do women (Kokko and Jennions 2008; Jokela et al. 2010). This discrepancy is largely due to opportunistic polygynous mating in societies where serial monogamy is considered the norm. Many traditional societies today still sanction polygyny, (even if serial monogamy is more common) and the strength of intrasexual violence in men co-varies with the relative presence of polygyny, meaning that intrasexual aggression is higher in societies where polygyny is sanctioned (Carter and Kushnick 2018). It therefore follows that men have a collection of adaptations related to competing for mates, while women tend to have a suite of adaptations to attract a mate and for this reason may compete less violently with one another. Women tend to compete with each other by making further changes or enhancements to physical appearance using: makeup, nail polish, tanning, plastic surgery, bras, corsets, and clothing. Men also enhance their appearance but not at the same rate and prevalence as women do (Puts 2010; Cross and Campbell 2011).

When women do engage in intrasexual aggression, it usually results in less violent consequences than it does in men. For example, gossip and ostracization can stigmatize rivals without escalating to physical violence. These acts do however inflict stress on the rival and act to besmirch the competitor's reputation – usually such gossip takes the form of belittling a competitor's physical appearance or casting doubt on her sexual reputation. Young women are more likely than men to question a rival's loyalty and draw attention to her infidelity (Milhausen and Herold 1999). Such tactics act to cloud paternity certainty and may give women who use them an advantage, especially if they do so while highlighting their own fidelity (Cross and Campbell 2011). These encounters can escalate to physical violence, when a female retaliates due to the besmirching of her sexual reputation. This escalation to violence is most likely to occur when resources are scarce, and women are impoverished (Cross and Campbell 2011).

When women do engage in violent intrasexual confrontation, it is usually less grievous than it is in men. As with males, intrasexual violence among women is most common in adolescence and young adulthood: US official crime statistics report 73% of attacks carried out by adolescent girls were on other girls (Cross and Campbell 2011). In a British study, 7% of women reported being attacked by another female in the preceding 5 years (George 1999). In both the UK and USA, female-female assaults occur most commonly between the ages of 15 to 24 year olds (Cross and Campbell 2011). The reasons for these attacks fall (either directly or indirectly) into these three categories: jealousy, retaliation for slander against sexual reputation, and competition for desirable partners (Ness 2004; Cross and Campbell 2011). Again, skewed sex ratios are implicated to explain rates of violent crimes. In African-American communities where the adult sex ratio is heavily skewed towards females, some argue that this ramps up competition between females for mates and thus results in more assaults among women (Cross and Campbell 2011). As presented in the previous section however, considerable evidence suggests that a female-biased sex ratio may result in

higher male-male competition (Schacht et al. 2014; Carter and Kushnick 2018). Though the two are not mutually exclusive and it could be that in certain societies, female biased sex ratios result in increased intrasexual violence in both sexes, or other ecological conditions are at play.

Other such ecological factors are resource availability, and men's resources seem to predict female intrasexual violence. In poorer communities, fighting for a well-resourced mate may be worth the risk, as the variance in income is much larger than it is in the middle classes. Where the differences in resources are negligible, such as between a Doctor and a Lawyer, the costs of engaging in violence may be greater. Overall, rates of intrasexual violence among women are much lower and less serious than that of men. Weapons are rarely used, and punching and kicking are the main modes of violence (Cross and Campbell 2011).

Conclusions

A re-evaluation of sexual selection theory in recent years has challenged some long-held assumptions, stemming further consideration of a multitude of factors – resulting in models that are more sophisticated (Kokko and Jennions 2008). Intrasexual violence and aggression reflected upon here make up only half of the sexual selection story, as intersexual violence or violence between mates occurs frequently (Cross and Campbell 2011). In addition, other adaptive and ecological problems may be solved by aggression that are still rooted in evolutionary theory but fall outside of sexual selection (Buss 2009). Social and cultural roles should be taken into account, but researchers generally agree – they are unlikely to explain the majority of sex differences in aggression – to assume so is committing human exceptionalism (Archer 2009). Intrasexual violence and aggression in humans, when contextualized with other taxa, can elucidate differences between males and females use of violence and aggression and can go some way to predict the patterning of violence and aggression generally.

Definition

Varying levels of investment results in different outcomes.

Introduction

There are a variety of situations in which investment results in a future payoff. This research falls into three areas of research: (1) mating versus parental investment, (2) quality versus quantity of offspring, and (3) cooperation.

Mating Versus Parental Investment

Parental investment is the investment in an offspring by a parent that benefits the offspring and comes at a cost for the parent (Trivers [1972](#), [1974](#)). In humans, females have obligatory gestation and lactation. Therefore, reproductive investment in offspring for females is greater compared to males. Because of this differential investment, females are typically highly selective in choosing mates (Trivers [1972](#)). Males on the other hand are not as selective. Since the females are choosing the mates, males invest in competition tactics that increases their likelihood to be chosen (e.g., mating displays, fighting; Cox and Le Boeuf [1977](#)).

Quality Versus Quantity of Offspring

One cost of parental investment is it decreases the investment in future offspring. Because of this, a trade-off must be made in quality or quantity of offspring (Kaplan [1996](#)). For example, as the number of offspring increases (i.e., higher quantity), the level of investment per offspring decreases (i.e., lower quality). According to life history theory, this tradeoff is influenced by cues of the external environment (Gangestad and Simpson [2000](#)).

For example, a child raised in a harsh environment is receiving cues that in the future access to stable pair-bonds and resources will be limited. Therefore, adopting short-term mating tactics,

reproducing earlier, and increasing the quantity over quality of offspring would be more beneficial. The opposite is true for children raised in an environment in which there was stable biparental care and resources available. It would be more beneficial for this individual to adopt long-term mating tactics, delay reproduction, and increasing the quality over quantity of offspring (Gangestad and Simpson 2000).

Cooperation

Unlike the trade-offs of mating vs. parental investment and quality vs. quantity of offspring, cooperation does not have an immediate payoff. Cooperation, especially altruism, has been a puzzle to many evolutionary psychologists. Cooperation is any behavior that gives benefit to someone other than the cooperator. There are two models that try to explain why, despite its lack of obvious benefit, it exists: kin selection and reciprocity.

Kin Selection. Kin-biased cooperation is one of the original theories that try to explain the paradox of cooperation (Darwin 1859; Hamilton 1964). It is found in a variety of species from primates to insects (Bourke 1997; Silk 2002). Kin selection predicts that individuals should preferentially help relatives over nonrelatives and should help according to the degree of relatedness. In order to preferentially help relatives, individuals must first be able to discriminate between kin and nonkin. Many social animals support this prediction and are able to discriminate between kin and nonkin (Griffin and West 2003). Additionally, there is a stronger discrimination of kin versus nonkin in species in which benefits of helping are greater (Griffin and West 2003). Kin selection is very powerful in cooperative breeding species, but it does not account for all types of cooperative behaviors.

Reciprocity. Although the theory of kin selection is widely accepted, other forms of cooperation such as reciprocity are less so. Reciprocity is the mechanism in which cooperative behaviors are favored by the probability of future beneficial mutual interactions. Reciprocity in a population will stabilize cooperation if the following

conditions are met: (i) the benefits to the recipient outweigh the costs to the donor, (ii) individuals interact repeatedly, and (iii) individuals recognize partners, therefore detecting cheaters. Humans evolved in large groups in which they likely spent their entire lifespan within in one to two primary groups. Therefore, in the environment of evolutionary adaptedness, there was a large probability that individuals would interact repeatedly. Even in modern day environments in which they bring strangers into the lab that will likely never see each other again, individuals still choose to cooperate even though cheating is initially more beneficial (Hamilton and Axelrod 1981). This suggests that humans have an evolved mechanism to favor cooperation.

One of the most successful strategies for reciprocity is Tit-for-Tat (Hamilton and Axelrod 1981). Tit-for-tat the strategy in which players start out cooperating and copies the other players behavior (e.g., if player one cooperates player two cooperates, if player one cheats player two cheats). It should be noted that although reciprocity has been shown in a variety of contexts (e.g., food sharing, grooming, mating opportunities), other alternative models may be at play (e.g., kin selection).

Conclusion

There are a variety of situations in which investment in one aspect results in a future payoff. This research falls into three related areas of research: (1) mating versus parental investment, (2) quality versus quantity of offspring, and (3) cooperation. Cooperation is a puzzle to evolutionary psychologist because it does not have an immediate payoff, yet it occurs in a variety of species. There are two models that try to explain why it exists: kin selection and reciprocity.

Definition

When the body contains insufficient levels of iron within the blood.

Introduction

Iron is essential for the maintenance and growth of all microorganisms, including the ones that reside within the human body (Denic and Agarwal 2007). Careful internal monitoring of iron levels has to be maintained as excess iron can damage cells and the body has no method of reducing the iron content of the blood (Steinbicker and Muckenthaler 2013). Though excess iron can damage the host, insufficient levels of iron are just as harmful and can lead to iron-deficiency anemia where red-blood cell levels are reduced.

Inadequate iron levels are the most prevalent micronutrient deficiency globally (Bailey et al. 2015) and is present across all ethnic groups (Denic and Agarwal 2007). Children, pregnant women, and women of childbearing age have an increased susceptibility to inadequate levels of iron, and women are twice as likely to suffer from iron-deficiency anemia than men, primarily the result of iron loss during menstruation (Denic and Agarwal 2007).

The cause of the global deficiency in iron has been argued to stem from the agrarian revolution 10,000 years ago. This is when human culture transferred from hunter-gather based food collection to relying more on agriculture (Denic and Agarwal 2007). This resulted in lower levels of iron being consumed, as the staple diet shifted

from meat (containing iron) to cereals. As a result, the human body, which had evolved based on a predominantly meat-based diet, was deprived of iron when culture advanced.

On an individual level within contemporary society, the cause of iron deficiency and iron-deficiency anemia differs according to country. It can either stem from diets consisting of few foods rich in iron (either resulting from unavailability or restricted diets such as vegetarianism) or through conditions/diseases that cause blood loss (Camaschella 2015).

The effects of iron-deficiency anemia can be difficult to detect and can be mistaken for general poor health. As iron-deficiency anemia impacts the oxygen supply in the blood, the effects are generally felt as a decrease of fitness and strength (Camaschella 2015). There is also evidence that this disruption within the blood supply leads to impairments in cognition, ability to concentrate, and occupational performance (Denic and Agarwal 2007). Though the symptomology of iron-deficiency anemia may be vague, the diseases that are linked with it can be severe and include illnesses involving the kidney, heart failure, intestines, and cancer (Lopez et al. 2016).

Fighting Infection

One controversial debate concerning iron deficiency is the degree to which it protects the host from certain infections (Tansarli et al. 2013). During the aforementioned agrarian revolution, community size and animal domestication increased dramatically, creating an environment which promoted the transmission of pathogens from animals to humans (Denic and Agarwal 2007). As iron is vital to the maintenance of microorganisms (including pathogens), it has been argued that human evolution has failed to adapt to the lessening iron in the human diet because iron deficiency provides an adaptive advantage for protecting the host from certain diseases (Denic and Agarwal 2007).

The evidence for this protective effect is limited due to the amount of empirical investigation within the literature (Tansarli et al. 2013). While

the amount of studies directly investigating the effect may be limited, the evidence that has been conducted appears to support the protective effect (Tansarli et al. 2013). An example of this is a study by Jonker et al. (2012) who analyzed Malawian children living in areas with higher risks of contracting malaria. They found that, after controlling for baseline iron levels, children with iron deficiency were less likely to have malaria after a year.

Another example is Wander et al. (2009), who conducted a study investigating the effect of iron levels on the risk of infection for Kenyan children. The results suggest that the restricted iron available in their diet had a protective effect from contracting infection, provided that the levels of iron had not dropped too far. This is due to evidence that differing severities of iron deficiency can also be detrimental to protecting from infection by comprising the effectiveness of cell-mediated immunity (Wander et al. 2009). This would suggest that the pressure of infectious disease in the immediate environment determines the efficacy of iron deficiency as a protective force (Wander et al. 2009).

Safety of Iron Supplements

When pathogens infiltrate the body, an immunological response reduces the levels of iron in the blood to diminish their growth and spread (Wander et al. 2009). As such there is considerable debate pertaining to the safety of providing iron supplements for individuals residing in areas that confer a higher risk of contracting infectious disease. As removing the iron supply for pathogens is a vital aspect of an immunological response, increasing the amount of iron in the body of the host could risk making the infection worse (Hurrell 2012).

One study especially highlights the dangers of the use of supplements in areas that have a high risk of certain infectious diseases. Sazawal et al. (2006) attempted to study the effects of iron and folic acid supplements on children from Pemba, Zanzibar. The study had to be finished prematurely following safety concerns relating to

increased mortality and hospital admission from the participants.

Conclusion

Poor levels of iron impair the ability of the blood to carry oxygen around the body. This manifests in feelings of fatigue, poor concentration, and generally poor fitness. Despite these effects on the body, humans may not have adapted from the change in diet (resulting from the agrarian revolution) due to an evolutionary advantage provided by poor levels of iron reducing the growth of pathogens that have gained entry to the body.

The evidence for this protective effect from infection requires further evaluation and evidence than is present from the current literature. This is especially the case regarding the safety of iron supplements in areas prevalent in infectious disease where the benefits of having slightly reduced levels of iron may be beneficial.

Iterated Prisoner's Dilemma Model

Kaleda Denton
UCLA, Los Angeles, CA, USA

Synonyms

[IPD](#); [PD](#)

Definition

The Prisoner's Dilemma is a non-zero-sum game played by two players in which each player decides between two options – cooperate or defect – with the payoffs dependent on the combination of choices. The best payoff for players occurs when they sucker their partners by defecting while their partners cooperate. The second best payoff occurs when both partners cooperate. The third best payoff occurs when both partners defect. The worst payoff occurs when a player gets suckered. In iterated, or repeated, Prisoner's Dilemmas, two or more players play multiple rounds in succession, and players are able to change their strategies in response to previous moves of their opponents.

Introduction

The Prisoner's Dilemma game was formulated in 1950 by Merrill Flood and Melvin Dresher of the

RAND Corporation and exemplified by Albert Tucker of Princeton University in terms of choices faced by two prisoners. The game acquired its name from a hypothetical dilemma faced by two criminals who are imprisoned and placed in separate rooms. Each is offered a deal: if one confesses (defects on the other prisoner) and the other remains silent (cooperates with the first prisoner), the defecting prisoner goes free and his cooperating partner gets 3 years in jail. If both prisoners remain silent (cooperate), both get 1 year. If both confess (defect), both get 2 years. In a classic article, Robert Trivers proposed that the evolution of reciprocal altruism could be modeled in terms of Prisoner's Dilemma games, asserting that "The relationship between two individuals repeatedly exposed to symmetrical reciprocal situations is exactly analogous to what game theorists call the Prisoner's Dilemma" (Trivers [2002](#), p. 23).

The Prisoner's Dilemma game can be generalized to any situation in which two players simultaneously decide whether to cooperate or to defect. If both players cooperate, they each receive reward R . If both players defect, they each receive punishment P . If one defects and the other cooperates, the player who defected receives the temptation payoff, T , and the player who cooperated receives the sucker's payoff, S . The payoff matrix between Player 1 (bold) and Player 2 (italics) is (Table 1).

In all Prisoner's Dilemmas, $T > R > P > S$. On each move, defectors who exploit cooperators fare better than two cooperators, who fare better than two defectors, who fare better than cooperators exploited by defectors. This creates a dilemma because although mutual cooperation pays off better than mutual defection, the choice to cooperate is irrational from an individual, self-interested perspective, because on each move, defecting reaps greater rewards than cooperating does no matter what move one's partner makes. Players gain more points by defecting than by

Iterated Prisoner's Dilemma Model, Table 1 Payoff matrix for Prisoner's Dilemma games

	<i>Cooperate</i>	<i>Defect</i>
Cooperate	R, R	S, T
Defect	T, S	P, P

cooperating when their partner cooperates ($T > R$) and when their partner defects ($P > S$).

The payoff matrix for Prisoner's Dilemma games distinguishes them from other social games. For example, the payoff matrix for Chicken is $T > R > S > P$ (e.g., players who stay the course (T) win big when the other player (S) chickens out to avoid harm; both players avoid harm when both chicken out (R), but both suffer a great deal of harm when neither chickens out (P)).

Iterated Prisoner's Dilemmas

Prisoner's Dilemmas may involve one exchange or a series of successive exchanges. In iterated Prisoner's Dilemmas, two or more players play multiple rounds in succession. To ensure that mutual cooperation yields a higher payoff than alternating cooperation and defection, the payoff matrix for iterated Prisoner's Dilemmas must also satisfy $2R > T + S$.

In iterated Prisoner's Dilemmas, players are able to change their strategies in response to previous moves of their opponents. Iterated Prisoner's Dilemmas are more challenging than one-shot Prisoner's Dilemmas because although the optimal strategy on each individual round is to defect, it is in players' interest to avoid repeated chains of low payoff P-P mutual defections. The rational choice is to defect on the last turn, because the other player will not have an opportunity to retaliate. However, knowing that it is optimal for their opponent to defect on the last turn, players will realize that the optimal move on the second to last turn is to defect, and so on, which will give rise to low-payoff P-P exchanges. In contrast to one-shot Prisoner's Dilemmas, the rational defection strategy pays off poorly in iterated Prisoner's Dilemmas and is rejected by most human players.

Notable Characteristics of Prisoner's Dilemmas

Prisoner's Dilemmas model problems in which individuals are faced with decisions between

pursuing their selfish interests at the expense of their partners or cooperating with their partners to maximize their combined gains. Prisoner's Dilemmas are challenging because the outcomes for each player depend on the choices made by the other player. In most contexts, the optimal outcome for two or more players considered as a group is to cooperate because a group of two or more cooperating players gains more than (a) groups of two or more selfish players ($R + R > P + P$) and (b) groups containing both selfish and cooperative players ($R + R > T + S$). However, paradoxically, on each move that players make, the optimal strategy is to defect. Individuals may choose to defect as an offensive strategy – to maximize their gains by exploiting their partners – or as a defensive strategy – to minimize their losses by avoiding being suckered. However, if both players choose to defect, both players end up with the second worst outcome – in effect doing one another down.

Prisoner's Dilemmas abound in the real world because people frequently encounter situations in which they are able to advance their interests in selfish ways that, if adopted by others, would produce undesirable results. Some examples are partners deciding whether to do their share of the housework, politicians deciding whether to go negative in campaigns, gas station owners deciding whether to lower their prices, and arms races.

Modeling Social Evolution with Iterated Prisoner's Dilemma Games

Game theorists have used Prisoner's Dilemma games to model the evolution of reciprocal altruism and other forms of cooperation. In a classic study, Axelrod and Hamilton (1981) contacted a number of game theorists and invited them to submit strategies for an iterated round robin Prisoner's Dilemma tournament that modeled the natural selection of social strategies. In Axelrod and Hamilton's tournament, the points won in each game represented offspring inheriting the winning strategy. Each round of the Prisoner's Dilemma game constituted one generation, and the winners (therefore the offspring) populated the next

generation. The strategies (or alleles) in each new generation competed against one another in an iterated manner for 200 generations. The “climate” of the population (the number of replicas of each strategy or allele) changed from generation to generation, because the most successful strategies became increasingly prevalent, and the less successful strategies diminished in number or became extinct. As winning strategies became increasingly prevalent, they interacted with replicas of themselves increasingly frequently. It follows that successful strategies had to fare well against replicas of themselves.

Axelrod and Hamilton's iterated Prisoner's Dilemma games modeled several basic principles of social evolution. Groups of two or more cooperators produced more offspring than groups of two or more defectors, and each member of the group of cooperators produced more offspring than each member of the group of defectors. However, within groups that contained both cooperators and defectors, defectors produced more offspring than cooperators did. Thus, Axelrod and Hamilton's contests captured the tension between between-group selection that favors the evolution of cooperation and within-group selection that favors the evolution of selfishness (Dugatkin and Reeve 1994).

Tit for Tat

Axelrod and Hamilton's initial simulations of the evolution of cooperation using iterated Prisoner's Dilemmas produced two main findings. First, “Always Defect” (the most selfish strategy) constituted an evolutionarily stable strategy – in other words, this strategy could not be defeated by any other strategy. However, even though “All-D” was stable, it paid off poorly, because as this strategy increased in number, it interacted increasingly frequently with replicas of itself, which produced low payoff (P-P) outcomes. Although evolutionarily stable, the “All-D” strategy was not optimal.

Another finding from Axelrod and Hamilton's tournaments ended up garnering a great deal of attention. Axelrod and Hamilton found that a

cooperative strategy called Tit for Tat could prevail over other strategies under certain conditions and indeed won the first tournament they sponsored. Players invoking the Tit for Tat strategy make a cooperative choice on the first move and in subsequent moves, copy their opponent's previous move. If their partners cooperate, they continue to cooperate; if their partners defect, they cut their losses by defecting. Axelrod and Hamilton found that Tit for Tat produced more offspring than “All-D” because it produced as many offspring as “All-D” did subsequent to the first exchange, plus a greater number of offspring in exchanges with other cooperative strategists, without suffering the costs of being repeatedly suckered. “TIT FOR TAT won the tournament, not by beating the other player, but by eliciting behavior from the other player which allowed both to do well. . . . So in a non-zero-sum world you do not have to do better than the other player to do well for yourself” (Axelrod 2006).

There is a great deal of evidence that contemporary humans employ Tit for Tat strategies in their everyday lives, as captured by expressions such as “quid pro quo” and “don't get mad, get even.” On the positive side, individuals are prone to help those who help them and to repay favors. On the negative side, the Tit for Tat strategy can give rise to blood feuds.

The Evolution of Nicer Forms of Cooperation

In a review of research on reciprocal altruism, Trivers (2006) wrote, “TfT and Axelrod and Hamilton (1981) spread like wildfire through the literature, so that soon all reciprocal interactions seemed to be formulated in terms of the PD [Prisoner's Dilemma]” (p. 70). In addition to game theory research employing human participants, investigators found that other species, including viruses and bacteria, engage in iterated Prisoner's Dilemma types of exchanges and employ Tit for Tat strategies to propagate replicas of themselves. However, as pointed out by Trivers (2006), “it soon seemed that theorists and empiricists alike were forgetting that iterated games of PD amount

to a highly artificial model of social interactions; each successive interaction simultaneous, costs and benefits never varying, options limited to only two moves, no errors, no escalated punishment, no population variability within traits, and so on" (p. 70).

In studies that followed Axelrod and Hamilton's simulations, researchers modified the conditions in which Prisoner's Dilemma games were played to reflect more validly the conditions in which strategies evolve in the animal kingdom. "Modifications to the IPD [iterated Prisoner's Dilemma] include variations in population structure, number of players, number of strategies, relatedness of players, stochasticity of strategies, stochasticity of environment, amount of memory, possibility of individual recognition, norms, ostracism, mobility of players, and mistakes by players" (Dugatkin 1997, p. 24). Follow-up studies found that several strategies were able to defeat Tit for Tat in environments that corresponded more closely to actual environments than those modeled in Axelrod and Hamilton's original research (Nowak and Sigmund 1992). One of the most significant findings from these studies was that the kinds of errors and random events that inevitably occur in the process of evolution may exert significant effects on the selection of social strategies. In particular, investigators found that the Tit for Tat strategy was vulnerable to selfish mistakes that launched iterated streams of low-gain defect-defect exchanges. For this and other reasons, most of the strategies that ended up winning modified computer contests were more cooperative or "nicer" than Tit for Tat – strategies that paraded under such banners as "Generous Tit for Tat," "Tit for Two Tats," "Firm but Fair," "Contrite Tit for Tat," and "Pavlov" (win-stay, lose-switch) (Ridley 1996). One of the main principles exposed by this research was that although unconditional cooperation is a losing strategy, several forms of conditional cooperation that enable players to cut their losses against cheaters can evolve in some environments. Other notable findings from studies following Axelrod and Hamilton's research were: (a) more than one strategy may evolve in some populations, and

strategies may fluctuate in the population because they are frequency-dependent, (b) strategies such as Pavlov that "learn" tend to defeat inflexible strategies, and reputation may play a significant role in learning (Ridley 1996), (c) ostracism may favor the evolution of cooperation (Hirshleifer and Rasmussen 1989), and (d) punishing defectors and establishing cooperative norms may facilitate the spread of cooperative strategies (Stephens et al. 1996).

Conclusion

The iterated Prisoner's Dilemma models problems faced by humans and other animals in which behaving selfishly is the rational choice on each individual round or encounter, but cooperating can reap greater benefits in the long run. After pitting different Prisoner's Dilemma strategies against each other in simulations of natural selection, theorists found that a cooperative strategy called Tit for Tat prevailed. Follow-up research that more accurately modeled natural selection found that even "nicer," or more cooperative, strategies than Tit for Tat could defeat Tit for Tat and evolve, primarily because they were equipped to correct never-ending strings of low payoff mutual defections.

1954; Charnov and Schaffer 1973; Stearns 1976). Both reproductive strategies are observed in the plant and animal kingdoms. Humans (*Homo sapiens*) are an example of iteroparous species – humans are biologically capable of having several offspring during their lives. Iteroparous vertebrates include birds, reptiles, fishes, and mammals (Angelini and Ghiara 1984). Among invertebrates, most Mollusca and insects (e.g., cockroaches and mosquitoes) present an iteroparous reproductive strategy (e.g., Fritz et al. 1982). Most perennial plants reproduce multiple times during their life span, thus are considered iteroparous species (Watkinson and White 1986).

Theoretical Models

The evolution of iteroparity (and semelparity) has been subject of several theoretical models. One set of models attempts to explain the differential evolution of iteroparity by examining the trade-offs between reproductive effort involved in offspring produced and offspring forgone (for a review, see Roff 1993). According to the trade-off models, the reproductive effort of an organism occurs optimally when the benefits of offspring produced outweigh the costs of offspring forgone. That is, the greatest distance states the optimal reproductive strategy for a given species. For species with higher life expectancy (i.e., low forgone offspring rate), the optimal reproductive strategy is to reproduce several times in a lifetime. Trade-off models have found limited supportive evidence from living systems. Moreover, the bet-hedging models investigate whether iteroparity was selected over the evolutionary time because it functions against unpredictable infantile survival rates (see Fox and Rauter 2003). The bet-hedging models have not found empirical support – in living systems, many semelparous species live in habitats with high environmental unpredictability.

The models based on demographic parameters have good support from living systems. Cole (1954) studied demographic explanations for the evolution of iteroparous and semelparous reproductive strategies. Cole's models resulted in an

Definition

A reproductive strategy characterized by multiple reproductive cycles over the course of a lifetime.

Introduction

The term *iteroparity* refers to a reproductive strategy characterized by multiple reproductive cycles over the course of a lifetime and contrasts with *semelparity* (see ► “*Semelparity*”). The iteroparous and semelparous reproductive strategies received special attention in the study of reproductive strategies of species (e.g., Cole

iteroparous species bearing annual litters of an average of three offspring having the same rate of population growth than a semelparous species that has one litter of four and dies afterward. This suggested that an advantage of just one offspring would select for semelparity. Charnov and Schaffer (1973) then identified that sensible variances in adult and infantile mortality were responsible for costs of a semelparous reproductive strategy that were not accounted by Cole's model. These demographic models have been successful when tested with real-world systems. That is, according to these models, humans are an iteroparous species because the benefits of devoting reproductive efforts to multiple offspring outweigh the risk of infantile mortality.

Conclusion

The iteroparous reproductive strategy played a key role in the evolution of human's reproduction and parenting systems (Jones 2009). Although optimal reproductive strategies may vary between species, theoretical models have shown that iteroparous species have higher life expectancy, making it more optimal for humans to devote reproductive effort to more than one reproductive occurrence in a lifetime.

Definition

A physical best known for his work in assisting suicide.

Introduction

Occasionally, history conveniently presents us with an event or a movement personified by a single man or woman. Such an occasion is the melding of Dr. Jack Kevorkian with the physician-assisted suicide (PAS) movement in the 1990s. Pathologist, author, musician, and painter, he is best remembered for having escorted at least 130 patients to their death by assisted suicide and euthanasia.

His Armenian parents had fled persecution in the Turkish Ottoman Empire and immigrated to Pontiac, Michigan, where he was born on May 26, 1928. He attended the University of Michigan

Medical School from where he graduated in 1952. Subsequent to graduation he entertained several radical ideas, including using death row inmates for medical experimentation, and transferring cadaver blood into living recipients, including himself (Nicol and Wylie 2006).

In 1990, he met a 54-year-old Janet Adkins, who became his first assisted suicide. He had cobbled together a homemade device he called a Thanatron (Greek for “death machine”), consisting of a mechanism that initially delivered IV saline, followed by a barbiturate, and finally a lethal dose of potassium chloride. Although initially charged with murder, there were no laws in Michigan that made assisted suicide illegal. The charges were dropped. As his activities increased, the state legislature frantically pieced together a law that made PAS illegal. However, the bill had been so poorly written that Kevorkian was tried four times between 1994 and 1997 and never convicted. But as the legislature had been unsuccessful in convicting him, they were able to deprive him of his medical license, thereby denying him access to controlled substances. From these circumstances, he contrived another mechanism, a Mercitron (mercy machine), that delivered carbon monoxide through a mask that permitted patients to initiate suicide (Jackson 2011).

Throughout his legal escapades, he was inextricably linked to his equally colorful attorney, Geoffrey Fieger. Mr. Fieger had gained such notoriety that he eventually, though unsuccessfully, ran for governor. Dr. Kevorkian continued to

push the limits of the legal system and eventually “fired” Mr. Fieger when he needed him the most, prior to his eventual conviction (Lessenberry 1994).

His last, most controversial patient was Thomas Youk, a 52-year-old with end-stage ALS who had requested his own death with the support of his family. Kevorkian had videotaped himself actively injecting Mr. Youk with a lethal dose of drugs. Through an intermediary, he had the tapes sent to CBS News where they were later aired nationwide on the television show - ‘60 Minutes’. This was not only flaunting the law, it was a departure from PAS to euthanasia, which was construed as second-degree murder by a Michigan jury. By refusing legal counsel and choosing to represent himself, he had lost opportunities to call witnesses and present useful evidence. Judge Jessica Cooper sentenced him to the maximum extent of the law, 10–25 years in prison. He eventually served over 8 years before he was paroled at the age of 79 due to good behavior and failing health (Schneider 2011).

Upon release from prison, Kevorkian was a much sought-after speaker and in 2008 ran for the US Congress, though only received 2.6% of the vote. His story was made into a critically acclaimed HBO movie in 2010, starring Al Pacino in the lead role for which he won an Emmy and a Golden Globe. Dr. Kevorkian died at 83, of natural causes and without artificial or mechanical assistance, on June 3, 2011.

Conclusion

Dr. Kevorkian’s notoriety was vast and varied. Hailed by some as heroic and others as fanatical, he nevertheless brought a meaningful and potent conversation from the dark ages into the twenty-first century.

An early meta-analysis showing that gender differences in aggressive behavior are moderate in

size but persistent, yet decreasing in magnitude, over the life span.

Introduction

Are men and boys more aggressive than women and girls? Janet Hyde (1986) conducted the first modern meta-analysis concerning this question. Meta-analysis is a quantitative statistical technique in which a researcher seeks to compute an estimate of an effect size. The effect size that Hyde (1986) sought to quantify was the magnitude of the gender difference in aggression, including physical aggression and verbal aggression. The effect size that Hyde used was Cohen's d , a standardized effect size. A standardized effect size is a ratio of the magnitude of the difference between groups, relative to how much individuals within a group vary from one another. Positive effect size estimates indicate that men and boys have higher levels of aggression than women and girls, and effect sizes of 0.20, 0.50, and 0.80 are considered small, medium, and large differences, respectively (Cohen 1988).

Building on her previous work (Hyde 1984) stemming from Maccoby and Jacklin's (1974) review, Hyde (1986) sought to apply newer meta-analytic techniques to the question. In particular, Hyde was concerned with testing and accounting for *heterogeneity*: the notion that characteristics of studies might be associated with differences in effect size estimates. The characteristics she examined were type of aggression, method of measurement, study design, and age of participants.

Type of Aggression

An important question in the literature historically has been whether there is a gender difference in aggression, depending on the type of aggression investigated (physical vs. verbal). Hyde reported that although the effect size for physical aggression appeared larger ($d = 0.60$, based on 26 studies) than the effect size for verbal aggression ($d = 0.43$, based on 6 studies), this difference

was not statistically significant. Both effect size estimates were positive, indicating that men and boys showed higher levels of both physical and verbal aggression than women and girls.

More recently, researchers have asked whether women and girls show more indirect or relational aggression than men and boys. Indirect aggression differs from direct (verbal and physical) aggression in that when directly aggressing, the perpetrator of aggression directly engages a victim, whereas with indirect aggression, the perpetrator seeks to harm the victim by damaging a victim's reputation. A more recent meta-analysis (Archer 2004) found a small negative effect size such that women and girls were more indirectly aggressive than men and boys, but this newer meta-analysis also replicated Hyde (1986), finding a positive effect size of moderate size for both physical and verbal direct aggression.

Method of Measurement

The method of assessment of aggression varied across studies in Hyde's (1986) meta-analysis. Most studies used direct observation (42 studies), whereas other studies used self-report (14 studies), parent or teacher report (8 studies), projective assessment (1 study), or peer report (4 studies). Hyde (1986) reported significant heterogeneity based on method of assessment, implying that there were differences in the effect sizes observed depending on measurement method. However, the effect size for self-report ($d = 0.40$) was not statistically smaller than the effect size for direct observation ($d = 0.51$).

Study Design

Hyde (1986) contrasted observational and correlational studies with laboratory experiments. In a true experiment, the researcher manipulates and controls an independent variable (in this case, usually a provocation to aggress) and observes its effects on a dependent variable (here, an aggressive behavior or cognition). In observational/correlational studies, a researcher tests for

an association between measured variables – in this case, typically gender and a self-report of unprompted aggressive thoughts or behavior.

In her meta-analysis, Hyde (1986) reported that effect sizes were larger in observational/correlational studies than experimental studies, with effect sizes of $d = 0.56$ (a moderate effect size) in 42 observational/correlational studies versus $d = 0.29$ (a small to moderate effect size) in 27 experimental studies.

Developmental Effects

Hyde (1986) reported that gender differences decreased in magnitude over the course of development. That is, gender differences were larger among preschool-aged children ($d = 0.58$) than they were among college students ($d = 0.27$).

It is noteworthy that in a more recent review of over 350 studies, Archer (2004) reported effect sizes of 0.56 for elementary school-aged children (ages 6–11), compared to 0.29 for emerging adults (aged 22–30 years), and -0.01 for adults over age 31. Importantly, Hyde (1986) explained that methodological factors in different studies (e.g., method of measurement, type of aggression studied) are confounded with age of sample, making firm developmental conclusions difficult.

Conclusion

Janet Hyde's (1986) meta-analysis was a groundbreaking work in early investigations of gender differences in aggression. The paper is important because it was one of the first to use newly developed tests of heterogeneity to determine whether effect size estimates for gender differences varied based on type of aggression, method of measurement, study design, and developmental period. Hyde reported that effect size estimates did vary based on study design and developmental period, but there were no significant differences between physical and verbal aggression, nor between studies assessing aggression using self-report versus direct observation. Overall, estimates were moderate in size

and positive in magnitude, indicating support for the notion that men and boys are generally more aggressive than women and girls.

From a modern vantage point, Hyde (1986) leaves some important questions unanswered. In particular, it fails to correct effect size estimates for publication bias, a well-known cause of overestimation in effect size. Archer (2004) reported some attempts to assess publication bias in this literature, but an update of this meta-analysis with more modern bias correction techniques would be warranted at this point.

Definition

Predictions about how cues to accelerated life history will be visible in maturation.

Introduction

Jay Belsky had a breakthrough moment – in his own words “the best idea I would ever have” – early in his career while teaching a graduate seminar. Having been trained in traditional developmental psychological theories (Freudian, attachment theory, and social learning theory) he was familiar with the idea that good developmental trajectories followed naturally from positive parental involvement. Parents who were responsive, financially and emotionally secure, and possessed of an acceptable level of intellectual and social skills would produce children who were similarly capable of love and social interaction in later life. A paper by colleague Pat Draper

(Draper and Harpending 1988) changed all that. Viewed from the perspective of life history theory, human notions of good and bad parenting take a back seat to effectiveness of passing genes on to the next generation – and this is true whether you are a human or a haddock. Viewed through this radical lens, violent and abusive human parents are preparing their offspring for a world where trust and love will not be rewarded. The fact of this being a social and moral evil says nothing about its being a reproductive dead end. This perspective, life history theory, has informed most of Belsky’s subsequent work.

Life History Theory

Life history theory is a set of well-validated interlocking biological predictions about the differential allocation of resources to different fitness-related aspects of an organism’s needs throughout its life. It is well-validated across a huge range of taxa. At the most basic level, organisms can be impelled down slow or fast life history paths. Slow paths are ones that emphasize greater time taken to reach maturity, the low acceptability of risk, and other modifications to take advantage of a predictable and supportive environment. On the other hand, fast life histories are favored in risky, dangerous environments where ultimate fitness is increased by maturing early and favouring reproductive quantity over quality. From a gene’s eye perspective, either set of strategies is as good as the other – both have been favored by selection to maximize fitness (Stearns 1976).

Human Development

Humans are obligate investors, and even minimum parental investment is still considerable. That said, there is plenty of opportunity for parents to cue offspring to a life of likely threats or opportunities. What Belsky realized was that what was traditionally regarded as bad parenting – e.g., unresponsive care-giving, spousal abuse, and frequent conflict was resulting in developmental

trajectories that likely maximized that child's fitness later in life.

This concept is not unknown to popular culture. In the classic country and western song "A Boy Named Sue," the father abandons his son at age three after naming him in a way that will ensure daily conflict. When they meet, later in life, and fight, they are reconciled over the realization that this treatment toughened the son up for the life he was to lead – the song even mentions his speed of maturation. This pattern (minus the sentimental reconciliation) is a distillation of Belsky's key insight as it pertains to what others would regard as developmental insults. Specifically, early maturation should be predictable from what others would regard as bad parenting (Belsky et al. 1991).

The implications of this are profound. The organism can be viewed as a fitness maximizer who can be conceptualized as saying (not consciously) to itself, "given that I am born into an environment that is harsh and unforgiving, in which I can't take my time to choose the best mate, ensure mutual commitment, and invest time and energy in healthy pursuits and a small number of much cared for children; my best reproductive bet is to start reproducing early, be a lot less choosy about with whom I do this, and have as many offspring as possible given that their chances of survival to reproductive maturity are so much less than they could be in this untrustworthy and unpredictable world." The question then is – what sort of early cues might set humans down one path rather than another. Given the need for biparental investment in our ancestral past, Belsky and others (e.g., Belsky et al. 1991) hypothesized that father absence in key developmental periods would predict earlier maturation.

These sorts of predictions have been confirmed strongly in females, but this is only part of the story. The mechanisms are far from perfect, and early calibrations of organisms to their likely environments might go awry. Genes that underlie these mechanisms may thus increase their fitness by hedging their bets somewhat. This results in a set of hypotheses about differential individual susceptibility (Belsky et al. 2007).

The observed effect of this is that some children are likely to appear more resilient to early markers of abuse than others. This is what we do find. Some children are highly reactive – with certain gene markers underlying these individual differences – and these children do both especially poorly in adverse conditions and especially well in supportive ones (Belsky 2012; Belsky and Pluess 2013).

Conclusion

Belsky has summed up these insights in terms of "biological gravity." Engineers cannot ignore the force of gravity when designing a building. Evolution is, similarly, a force that cannot be ignored when considering how biological organisms are designed. And, ultimately – this is cashed out in terms of differential survival of genes. The nature/nurture debate itself needs to grow up.

Synonyms

Emotional jealousy; Male sexual jealousy; Platonic jealousy; Sexual jealousy

Definition

Jealousy is a cognitive or emotional response of insecurity or inferiority that occurs when there is a perceived threat to a valued social relationship, resulting in actions that mitigate the threat.

Introduction

Jealousy refers to a cognitive or emotional response of insecurity or inferiority that occurs when there is a perceived threat to a valued social relationship, resulting in actions that mitigate the threat. Different types of jealousy are based on different contexts under which threats to relationships occur, including intimate relationships, siblings, rivals, friends, and peers.

Sexual and Emotional Jealousy

Sexual and emotional jealousy within romantic relationships seems to have evolved in response to conflicting interests between the sexes. Due to concealed ovulation, men faced uncertain paternity and the possible investment in their rival's offspring, known as cuckoldry risk. Since many humans form long-term pair bonds, cuckoldry risk significant loss of time and resources to raising unrelated offspring. Traits that identified and reduced the risk of cuckoldry, such as sexual jealousy, would have been adaptive; thus, sexual jealousy may function by protecting paternity in men (Buss 1992; Trivers 1972; Daly et al. 1982).

Women, on the other hand, have 100% certainty in maternity, so they did not have the same risk of unknowingly investing in genetically unrelated offspring (Buss 1992). However, women risked losing their partner's time, resources, and abandonment to other women (Daly et al. 1982). Because of this risk, women may have evolved to be more susceptible to emotional jealousy (see ► "Emotional Jealousy"). Sexual and emotional jealousy can be understood as an adaptive response to sexual conflict, which is when reproductive interests of the sexes do not align (see ► "Sexual Conflict Theory (Middle-Level Theory in Evolutionary Psychology)").

There is a large body of evidence to support sex differences in these types of jealousy. For example, women are more distressed by scenarios involving emotional infidelity and the possibility of their partner directing affection elsewhere, whereas men are more distressed by scenarios involving sexual infidelity and possible cuckoldry situations (Buss 1989, 1992, 1995; Wiederman and Kendall 1999). These patterns emerged using both self-report and electrodermal measures and confirmed using meta-analyses (Sagarin et al. 2012).

Jealousy may be more pronounced in committed relationships due to the amount of time and resources it takes to form and maintain such a relationship (Harris 2003). There appears to be an increase in the use of mate guarding tactics as relationships increase in duration and seriousness (Buss 1988). Relationship experience impacts jealousy responses among men, where 55% of men with experience in committed sexual relationships, compared to 29% of men with no such experience, reported they would experience greater distress over sexual infidelity (Buss 1992). Among women, the impact of emotional infidelity was not impacted by their history of committed sexual relationships.

Historically, infidelity was often illegal with punishments as severe as death, highlighting the importance that men, who largely or exclusively controlled judicial systems, placed on marital fidelity. Examples of such punishments were found cross-culturally, including European, African, Central American, and Mediterranean cultures (Bullough 1976; Daly et al. 1982).

Jealousy may motivate various actions to secure exclusive access to one's mate, and these actions differ between the sexes. For example, since women's mating strategies involve being more selective based on a potential mate's resources, men who engage in resource display are more likely to retain their mate. Men are also more apt to use violence or threats of violence as a form of coercive control (Wilson et al. 1995). Buss and Shackelford (1997) found that men with younger, more attractive mates were more likely to engage in mate guarding, resource display, and violence in order to retain mates, likely because these women are of higher reproductive value at that age, motivating greater competition for them.

In contrast, women's jealousy may motivate them to enhance their appearance. Appearance enhancement functions by modifying physical attractiveness to appear more youthful, and thus more fertile, to garner stronger interest from a partner (Symons 1979). Similar mating strategies are more pronounced when women have a mate with greater resources. Women in relationships with lower-income men are less likely to engage in vigilance and respond less severely to intrasexual threats (Buss 1988; Buss and Shackelford 1997; Daly et al. 1982). There is some information to suggest women may obtain an equal or greater benefit by choosing a partner whose resources are considerable enough to support multiple mateships (Buss and Shackelford 1997).

Both sexes may engage in behaviors meant specifically to incite jealousy in their partner, known as *jealousy induction*. The most common methods of induction are flirting with members of the opposite sex, making comparisons to past relationships, and infidelity. It is reported, by both men and women, that the goal of such acts is to increase the security of their relationship and retain their chosen mate by increasing their motivation to protect that mate (Mattingly et al. 2012; Wegner et al. 2018).

Jealousy can sometimes lead to positive outcomes, such as signaling partner investment, but there is also a significant risk of negative outcomes, such as abuse, physical violence, and even homicide. It has been found that sexual jealousy is the

leading cause of violence among romantic partners, and sexual jealousy in men is the primary motivation behind physical violence like homicide. Psychological mechanisms associated with emotional and sexual jealousy sometimes malfunction, leading to pathological jealousy (see ► [“Jealousy: Psychiatric Diagnosis”](#)).

Siblings

Jealousy also provided an adaptive function for sibling relationships. Jealousy is triggered when exclusive access to parents is threatened by a new sibling who also wants exclusive access (Buunk and Bringle 1987; Hart 2018). According to Trivers (1974), jealousy between siblings can be attributed to discrepancies over how parent resources are directed. Since parental resources are limited, especially in ancestral environments, conflict arises when there is a change in how those resources are allocated. This conflict is particularly prevalent when a child is first introduced to a new sibling. The firstborn child risks a reduction in access to its mother's breast milk or a premature weaning in order to accommodate the new sibling. Reducing intake by sharing food and nutritional resources would have increased the chance of death, and so protecting exclusive access to those resources would have been adaptive for children and infants (Hart 2016a, b, 2018). Supporting this view, shorter intervals between births increase the likelihood of infant mortality. If a new sibling was born within a time period of 2 years, the risk of death for infants increases by up to 50%. The US Agency for International Development, whose work assists in assessing infant mortality and health, has even suggested parents try to restrict birth intervals to 3 to 5 years and 2 years at minimum (Berg and Brems 1989; Conde-Agudelo et al. 2012; Fotso et al. 2013; Thapa et al. 1988; United States Agency for International Development 2002).

Rivals

Jealousy may occur in other contexts, such as professional, occupational, and social relationships.

According to Buunk et al. (2010), jealousy in professional environments may be a response to intrasexual competition. For example, since women prefer men who have greater resources, status, and physically and socially dominant characteristics, men compete with one another in these domains. Meanwhile, women compete in domains involving physical appearance (Buunk et al. 2010; Campbell 2004). Therefore, high status and physical dominance invoke jealousy between men, whereas traits relating to appearance would invoke jealousy between women.

There are several lines of research to suggest that jealousy occurs between rivals over social communal qualities (i.e., interpersonal skills in groups), because those who are adept at such skills may threaten other people's inclusion in a group or may deny their advancement and promotion within a group. We place importance on our status in occupational settings because inclusion and status in a group have significant benefits. Individuals may seek to protect relationships with supervisors because supervisors make decisions about employee status. Jealousy is invoked when an individual believes a rival has more desirable characteristics or performs in ways that are viewed more favorable by a supervisor.

Jealous reactions in these contexts lead to various actions, including gossip, which is used as a potential source of damage to inclusion, status, or advancement a group, potentially enhancing one's own opportunity for advancement (Buunk et al. 2010; Buunk and Dijkstra 2015; Leary 1990; Zurriaga et al. 2018). Studies also suggest that these phenomena are found cross-culturally. In Dutch, Argentinian, and Kurdish samples, all groups were found to be primarily concerned and jealous toward rival characteristics, with men reporting jealousy toward social power and physical dominance, whereas women reported on feelings of jealousy directed at physical attractiveness (Buunk et al. 2010; Buunk 2015).

Friends and Peers

Being part of a social group increases the likelihood of survival due to the protective, psychological, and

material benefits of group membership. Protecting these relationships from external threats would serve to increase one's fitness; therefore, jealousy can function to protect group relationships, like friendships (Hill 1987; Hill and Davis 2000; Leary 1990). While friendships do not carry the same fitness benefits as do sexual relationships, they may help with solving other adaptive problems, such as acquisition of food, shelter, and introduction to potential mates. Bleske and Buss (2000) found that friendships also provided a psychological outlet, a boost self-esteem or self-worth, and insight into members of the opposite sex.

People also experience jealousy of opposite sex friends because it seems as they are viewed as potential mating partners and sources of sexual contact (Bleske and Buss 2000). Both men and women display regular attraction to opposite sex friends, with men reporting slightly higher levels of attraction than women. Women also showed a greater distinction between sexual relationships and opposite sex friendships. However, these friendships were generally found to be kept separate from one another for both sexes (Kaplan and Keys 1997; Sapadin 1988). Since these friendships sometimes lead to possible mateships, it would make sense that protecting access to these friends would be adaptive; thus jealousy serves the purpose keeping access to potential mates through friends.

Limitations to Jealousy Research

There are several limitations to research on jealousy. For example, a number of studies exploring distress responses in men and women toward emotional and sexual infidelity rely heavily on imagined scenarios, and while some have used physiological measures such as electrodermal activity and heart rate, there still remains a gap in the literature on this subject (Buss 1992, 1995). Furthermore, much of the current body of evolutionary research relies on individuals from samples of undergraduate students who may not have as strong a need for mate retention and guarding compared to older adults in committed relationships (Buss and Shackelford 1997). Despite the

vast amount of effort dedicated to understanding the differences between the two sexes on the activation and function of jealousy and how they react, there is little explanation on jealousy among same-sex samples, variability of jealousy within each sex, and how cultural variation may impact variation in jealousy. For example, in Kurdish samples, there was a surprising lack of difference between men and women on the scenarios and rival qualities that would evoke jealousy and competition (Wiederman and Kendall 1999; Buunk 2015). Furthermore, much of the research relies heavily on self-report measures which introduces response and reporting biases (Buss 1988), focuses on emotional and sexual jealousy, and pays little attention to jealousy between siblings, friends, and co-workers.

Conclusion

There is a fairly large literature supporting jealousy as an adaptation in response to threats to social relationships. More specifically, there is support for jealousy functioning as a mechanism to protect valued, usually sexual, relationships. Theoretical and empirical work have focused on intimate relationships and are mostly based on self-report assessments. Future work in this area would benefit from considering jealousy in other contexts, such as between siblings, friends, and co-workers.

Synonyms

Emotional jealousy; Emotional unfaithfulness; Extradyadic involvement; Sexual jealousy; Sexual unfaithfulness; Unfaithfulness

Definition

Infidelity is defined as unfaithfulness to a primary partner, which can take the form of a sexual and/or emotional extradyadic involvement with another person. Jealousy is explained as a reaction to threat to the relationship, reaction to loss of a partner, or response to a degradation of relationship’s individual values. This reaction can be triggered by real and/or potential rival.

Introduction

In various studies, infidelity has been related to disintegration of relationships across different cultures and societies. It has also been identified as one of the most common divorce predictors in the world (Hall and Fincham 2006). In general, infidelity tends to evoke strong feelings of jealousy. Evolutionary psychology distinguishes between sexual and emotional jealousy and infidelity. Emotional jealousy focuses on partner’s real or potential emotional involvement with a third person, while sexual jealousy is elicited by partner’s real or potential extra-pair sexual relations.

It has been claimed these two types of jealousy evolved in part due to selective pressures, namely as a response to sex-specific problems linked to reproduction. In humans, although there exists significant paternal care, minimum women's investments into reproduction are considerably higher than men's (pregnancy, childbirth, lactation, childcare, and protection), while male contribution can be minimal, in the form of sexual act. In the case of woman's sexual infidelity, the primary partner risks investing his resources in offspring who may not be genetically related to him, resulting in a loss of his reproductive success. Men thus face the adaptive problem of paternity uncertainty. Nevertheless, recent research shows that greater sexual jealousy in men may be driven by fears of loss of paternity opportunities more than by paternity uncertainty (Edlund et al. 2019). Women, on the other hand, in case of men's emotional infidelity are at risk of loss of time, resources, and partner commitment. Women therefore tend to prefer men with whom they can form an emotional connection and who can provide them with sources that increase the survival chances of their offspring. As a result, jealousy develops as an adaptive mechanism in both men and women who perceive threat to their reproductive success and it motivates behavior aimed at reducing that threat (Buss et al. 1992).

A considerable body of evidence suggests that while the magnitude of sex differences can vary, the existence of sex differences in jealousy is culturally universal (e.g., Harris 2002). In particular, women tend to feel more threatened by partner's emotional involvement, while men tend to respond more to a sexual threat (e.g., Buss et al. 1992; Edlund and Sagarin 2017; Harris 2002; Sagarin et al. 2012). In general, it has been argued that jealousy has three main aims: (1) it warns individuals about threats to a relationship, (2) alerts to possible same-sex competitors, and (3) prevents partner infidelity and relationship abandonment by modification of one's own behavior.

Jealousy

Although there are many different definitions of jealousy in romantic relationships, all agree on

viewing it as a reaction to the relationship being compromised. One of the basic definitions describes jealousy as one of the most common automatic responses to a threat posed by a third party (Buunk 1997; Dijkstra and Buunk 2001). The perception of threat arises from suspicion of actual or potential affection between one's partner and a rival (Dijkstra and Buunk 2001).

My Sex, Partner's Sex, or Rival's Sex: Three Main Explanations of Differences in Sexual/Emotional Jealousy

In studying jealousy from an evolutionary perspective, three main explanations of differences between men and women in their experience of sexual/emotional jealousy have been proposed. The first explanation, mentioned above, suggests that the type of jealousy depends on an individual's biological sex.

A pioneering study in this area was conducted by David Buss and his colleagues (1992). They used a forced-choice design where respondents were supposed to imagine their partner being interested in another person and asked to specify whether they would feel more upset by the idea of their partner falling in love with another person or by partner's sexual involvement with someone else. The results showed that 60% of men would be more upset by sexual infidelity, while only 17% of women chose sexual infidelity as the worse scenario. Regarding emotional infidelity, 83% of women and 40% of men chose it as being the worst case. Numerous other studies produced similar results. The forced choice method leads to relatively clear and easily repeatable results which seem to correspond to sex differences in response to jealousy stimuli (Carpenter 2012).

Some recent studies, on the other hand, work with the assumption that jealousy depends on partner's biological sex (e.g., Harris 2002). Specifically, several studies on homosexual individuals show that homosexual men tend to feel more anxious about the idea of partner's emotional infidelity and homosexual women about the idea of sexual infidelity of their partners. This seems to support the hypothesis that sexual/emotional jealousy depends on the biological sex of one's partner. The authors explain this finding by the fact that even though homosexuality and

homosexual behavior does not lead to direct reproduction of an individual, the mechanism of sexual selection will work in a similar way in homosexual men and women as in heterosexual individuals (Lippa 2007). In this case, the type of sexual/emotional jealousy would depend purely on the partner's biological sex, and sexual orientation should not play any role.

A third possible explanation of differences in experiencing sexual/emotional jealousy suggests that these different types are linked not to partner's biological sex, but rather to the potential rival's biological sex. Sagarin et al. (2012) showed that sex differences are present only in heterosexual individuals when they imagine their partner's infidelity with a person of the opposite sex who is reproductively compatible (similarly Frederick and Fales 2016; Sheets and Wolfe 2001).

Infidelity

There are many different definitions of infidelity, ranging from those limited to defining dichotomous sexual/emotional infidelity to those giving concrete accounts of activities which fall under the term infidelity (Brand et al. 2007). Recent literature often distinguishes between *sexual infidelity*, i.e., extradyadic sexual behavior without emotional involvement, and *emotional infidelity*, which refers to romantic feelings without sexual involvement to a person other than the primary partner. This typology does not exclude the possibility of these infidelities occurring simultaneously. Infidelity thus cannot be defined as a phenomenon or condition that has in all cases certain objectively existing characteristics. It seems therefore that from the perspective of the person who is cheated on, infidelity falls into the category of a subjective experience (Luo et al. 2010).

According to Luo et al. (2010), most studies do not offer a comprehensive definition of extradyadic behavior. The issue of different types of infidelity, i.e., what infidelity is and what it is not, and responses to them is difficult to grasp in quantitative studies, since the typologies presented cannot consider everything a person

could think of as infidelity and cannot take into account all possible reactions to infidelity in real life.

Definitions of infidelity commonly applied in research can be grouped into three broad categories: infidelity as sexual intercourse, infidelity as extradyadic sexual activity, and infidelity as emotional betrayal (Moller and Vossler 2015).

Infidelity as Sexual Intercourse

The definition of infidelity as having sexual intercourse with a person other than the primary partner is commonly used by large studies on the prevalence of infidelity (Whisman et al. 2007). This definition, however, fails to capture the experience of people who are involved in other than traditional exclusive relationships, for instance, open-relationship couples, such as polyamoric relationships, swinging couples, or some homosexual individuals (Moller and Vossler 2015). The definition also seems to assume that sexual intercourse has one generally understood meaning, while research shows that the meaning associated with expressions of sexuality depends on various factors, including context and culture.

Infidelity as Extradyadic Sexual Activity

Contrary to the previous definition, infidelity is understood not only as sexual intercourse with a other person than the partner, but also as other extradyadic activities. In previous studies on extradyadic behavior, all of the following has been classified as infidelity: masturbation in the presence of another person, oral sex, engaging in sex games, kissing, flirting, visiting strip clubs, watching pornography, and sexual fantasy about a person other than the primary partner. Furthermore, internet behavior that can be defined as sexual infidelity includes cybersex, the exchange of one's own sexual photos, online dating, online flirting, and the use of online pornography (Whitty 2003).

Infidelity as Emotional Betrayal

Emotional infidelity has been defined variously, for instance, as falling in love with another person or deep emotional attachment to another person, investment and dedication of love, time, and attention to a person other than primary partner,

or sharing confidential information (Luo et al. 2010).

This overview of the definitions used in various studies highlights the absence of a consistent definition of partner infidelity (Moller and Vossler 2015). Existing inconsistency in research definitions leads to significant differences in reported prevalence of infidelity, with lifetime prevalence ranging between 1.2% and 85.5% (Luo et al. 2010).

Prevalence of Infidelity

In general, it is believed that if an individual is in a long-term relationship, sex and intimate intercourse will be limited solely to the primary partner. Although previous research shows that infidelity is considered immoral, unethical, and unacceptable in the United States (Boekhout et al. 2003), statistics show that 2–4% of the population commit it annually (Treas and Giesen 2000; Whisman et al. 2007). A recent meta-analysis of 50 studies had shown that 34% of men and 24% of women have engaged in extra-marital sexual activities (Tafoya and Spitzberg 2007).

Although one can find cultural differences in the prevalence of infidelity, one type of infidelity is universal, namely *mate poaching*, meaning the effort to attract a person who is already involved in a different short- or long-term relationship (Schmitt 2004). According to Schmitt (2004), 70% of individuals have encountered someone who tried to poach them, while 60% of men and 40% of women admitted to trying to poach someone else's partner. To prevent mate poaching, there evolved an adaptation for *mate guarding*, i.e., the behavioral strategies used to ensure romantic partner's fidelity. Mate-guarding behavior can vary and range from vigilance to violence. Its main trigger seems to be sexual jealousy (Buss et al. 1992).

Correlates of Infidelity and Jealousy

Different and inconsistent results of studies on jealousy and infidelity may be due to various

definitions of romantic jealousy and infidelity and/or by the complexity of individual and relational factors which influence the experience of jealousy and infidelity.

Individual Factors

A large body of evidence associates sex with infidelity, especially in men. Some studies show that men tend to be the ones who commit sexual infidelity in long-term partnerships/marriages, and who also more frequently engage in online infidelity (Luo et al. 2010). Moreover, according to Boekhout et al. (2003), men are better at separating sexuality from love. More recent studies, however, show that differences in the prevalence of reported infidelity between men and women are diminishing (Brand et al. 2007). According to Whisman et al. (2007), men and women under the age of 45 report identical rates of extradyadic behavior but reasons for committing infidelity differ between the sexes. Men are more likely to seek sexual diversity, while women often resort to sexual infidelity as a way of acquiring a new romantic partner. Women who are unhappy in a partnership are more likely to commit infidelity and select partners who appreciate their attractiveness and make them happier (Brand et al. 2007).

Other commonly studied factors that can influence the experience of jealousy and infidelity are personality traits. Research indicates that jealous people show high levels of neuroticism, hostility, and social anxiety, which points to an anxious-ambivalent attachment style that is also associated with higher levels of jealousy (Buunk 1997).

Mate value discrepancy (MVD) is another factor that tends to be associated with forgiveness in romantic relationships. In particular, persons who perceive their partner's *mate value* as higher than their own are more likely to forgive their partner's indiscretions. Furthermore, the higher the value of the partner, the more likely it is that the lower-value partner experiences jealousy (Sidelinger and Booth-Butterfield 2007).

Qualities of the potential rival can influence the experience of romantic jealousy. Persons who perceive someone as a rival try to assess the threat such rival poses to the relationship by comparing rival's qualities to their own, by comparing qualities which are of importance to the romantic

partner, and by assessing how much of a threat the rival poses to the relationship and their self-esteem (Dijkstra and Buunk 2001). According to some studies (e.g., Massar et al. 2009), jealousy in men is caused mainly by rival's characteristics which are related to status. This is explained by the fact that in long-term relationships, women particularly value social status. Men are therefore are jealous of rivals whose socioeconomic status is higher than their own. Moreover, Massar et al. (2009) showed that a higher socioeconomic status is related to height, which is also why men are more prone to being jealous of higher rivals. In women, jealousy is elicited mainly by physically attractive rivals (in terms of body curves and facial features). This is because men tend to be attracted to young and physically attractive women, in other words to qualities that indicate women's fertility. A more attractive rival can therefore pose a more serious threat.

Another important factors related to infidelity are sociodemographic characteristics, such as the place and region of residence. Some studies indicate that persons living in large urban areas are more likely to engage in some form of extradyadic behavior than persons who live in rural areas (Treas and Giesen 2000). Thus, infidelity is also often seasonal: most frequent extradyadic behavior takes place in the summer, mainly because it is a travel-related time of the year. Travel offers opportunities for engaging in extradyadic sex away from one's place of residence, thus reducing the likelihood of being discovered (Adamopoulou 2013). There is no consensus on how religion and beliefs influence the occurrence of extradyadic behavior (Liu 2000; Martins et al. 2014). The relationship between the level of education and tendency to commit extradyadic behavior is also not unclear. Some studies suggest that more educated individuals tend to cheat more (e.g., Treas and Giesen 2000). Other studies, however, do not confirm this correlation (e.g., Martins et al. 2014).

Another important individual factor is sociosexual orientation. Research suggests that although people have generally negative attitudes towards infidelity, many commit it. It also seems that the higher the tolerance of individuals to the notion of infidelity is, the greater the chance to engage in extradyadic behavior in future (Liu

2000). Previous experience with engaging in infidelity has been repeatedly proven to be a significant predictor of extradyadic behavior in future (Adamopoulou 2013). In a study by Rodrigues et al. (2017), individuals who had experience with sexual infidelity had higher sociosexual desire, were less engaged in their primary relationship, and were more tolerant of various forms of infidelity. This study also found a complementary correlation, namely that individuals who had no experience with sexual infidelity were more involved in the relationship and had stricter views on infidelity.

Relationship Factors

Another possible explanation for infidelity is the *investment model* (Rusbult 1983). According to this model, three factors form the key components of romantic relationships: satisfaction in the relationship, investment in the relationship, and alternative options one may have. People who are satisfied in their relationship, had invested in their relationship, and are not aware of better alternatives are more likely to be highly committed to the relationship and therefore less prone to extradyadic behavior (VanderDrift et al. 2012). A correlation between infidelity and relationship quality has been found especially in marriages and partnerships of long duration where partners share households. It has been found that when such relationships become stereotypical and marital/partner benefits (e.g. sexual intercourse) become less frequent (Traent et al., 2007), and/or individuals experience lower relationship satisfaction, respondents list it as one of the main extradyadic motivators (Maddox Shaw, Rhoades, Allen, Stanley & Markman, 2013). In women, both married and cohabiting ones, some studies claim that the longer they are in a relationship, the more likely they are to engage in some form of extradyadic behavior (Træen et al. 2007).

Conclusion

Evolutionary psychology makes a distinction between sexual and emotional jealousy. Numerous studies found that there are differences between men and women with respect to these

two types of jealousy. Explanations of this phenomenon point to different reproduction investment in men and women and threats that arise from this disproportion. In general, men tend to be more distressed by the idea of sexual infidelity, whereas women tend to be more distressed by emotional infidelity. The idea of a strict correlation between one's sex and the type of jealousy has, however, been under some criticism. Varying and inconsistent results and explanations seem to point to numerous problems related to methodology and data analysis. Most quantitative studies which focus on jealousy experience neglect the wider context. For example, they do not take into account the incentives based on which respondents choose to answer. It may not be entirely clear whether they are comparing their priorities within the current relationship, past relationships, or base their responses on a purely hypothetical situation. According to some studies, answers may be influenced by the length of the relationship (e.g., Davis et al. 2018), but other studies do not confirm this result (e.g., Frederick and Fales 2016). Another problematic factor may be the choice of the research method itself. Results may vary depending on whether a quantitative or qualitative method of data collection is used. Carpenter's meta-analysis (2012) of 54 articles about the experience of sexual/emotional jealousy indicates that in general, the results were not fully consistent with the evolutionary explanation. Specifically, Carpenter's analysis had shown that when forced-choice measure was applied, both men and women were more likely to identify emotional infidelity as the worse option. When, however, a continuous scale was used, both sexes reported sexual infidelity as being more upsetting. Nevertheless, a recent review of different methodologies used to study romantic jealousy and other meta-analyses confirmed sex-specific differences in experiencing sexual/emotional jealousy (Edlund and Sagarin 2017).

There are various definitions on romantic jealousy and infidelity, and they lead to different figures on the prevalence of extradyadic behavior. This is exemplified, for instance, by a study of Brand et al. (2007) whose results indicate a similar prevalence of sexual infidelity in both sexes.

Another factor which influences the experience of jealousy and the likelihood of engaging in extradyadic behavior are cultural aspects. According to some studies, jealousy is culturally conditioned and sex differences are based on sex-specific socialization, which affects the perception of various jealous stimuli (Sheets and Wolfe 2001). As described above, motivators of infidelity differ between the sexes, while individual and relational factors are a crucial component of the jealousy experience and of willingness to engage in extradyadic behavior and should be therefore considered in future research.

Jealousy: Developmental Trajectory

Kristina M. Tilli and Joseph A. Camilleri
Westfield State University,
Westfield, MA, USA

Introduction

Jealousy typically refers to an emotional response that occurs when an interpersonal relationship is impacted by another person (Campos et al. 2010). This experience may be adaptive because it provides an alert of potential threats to an intimate relationship that would impact fitness (Campos et al. 2010). Jealousy can also function by protecting social relationships that enhance fitness at particular points in an individual's life

(Dillon 2013). The recognition of a potential rival triggers both negative affect and overt behaviors, such as imitation of the rival, aggression toward the rival, and attempts to redirect a loved one's attention to oneself (Dillon 2013). The developmental trajectory of jealousy is not well-researched; however, cross-sectional research shows how jealousy is manifested during different periods of development.

Jealousy in Infancy

There is conflicting opinion around the capacity for an infant to experience and express jealousy because scholars disagree on whether infantile emotional experience is limited to basic emotions such as joy, fear, sadness, anger, distaste, surprise, and possibly pride and shame (Campos et al. 2010). It is unclear how much social awareness is required to experience jealousy. Research examining jealousy in the first year of life may oversimplify the construct, and behavioral demonstrations of jealousy are not well differentiated from other possible emotional experiences.

Early in human development, survival depends on parental investment. Infants have a high level of dependency on a caregiver, typically the mother. Parental investment is reduced if there are siblings, thus, Dillon (2013) suggested that infants may exhibit jealous behavior to direct parental care away from their siblings and onto themselves. Jealousy is not limited to mothers attending to siblings but also to mothers attending to other social rivals (Mize and Jones 2012). It is difficult to ascertain whether infants are exhibiting jealousy or if they are expressing some other emotional indicator (Campos et al. 2010). However, studies have identified observable behavior patterns presumed to be the response to feelings of jealousy, due to the context of the behaviors (see Dillon 2013; Hart 2010).

Early research on infant responses to loss of maternal attention has found that infants tend to exhibit approach behaviors and negative affect more so when the loss of attention is to a rival. Mize and Jones (2012) found that infants ages 11–14.5 months old gazed more toward the

mother, stayed closer, and had more physical contact in the presence of a social rival (i.e., life-like doll). The infants also exhibited more anxiety and aggression, as well as negative affect and vocalizations. If negative vocalizations did not regain the attention of the mother, the infants would switch to positive vocalizations. Attempts to regain the attention of the mother in social rival conditions, but not conditions where the loss of maternal attention is to a nonthreatening object, suggests infants attempt to protect maternal attention when they perceive a social threat. This study replicated results from previous studies, suggesting it is a robust effect (Hart and Carrington 2002; Hart et al. 1998).

Infant jealousy may still be adaptive in modern environments. While resources in general are not as scarce as they were in ancestral environments, child mortality rates are still consistently affected by birth spacing and maternal fertility (Hart 2010). Particularly in developing countries, close age spacing of children contributes to early termination of breastfeeding (Hart 2010). Children born within 2 years of a previous birth are twice as likely to die (Hart 2010). Termination of breastfeeding prior to the first year of life also increases the risk of death, compared to those who continue breastfeeding (Hart 2010). Jealous responses in infants appear to have a survival function because it emerges in response to a valid threat of a peer or sibling, not nonthreatening stimuli such as inanimate objects or other adults. Parental investment is still necessary for infant survival, and even in modern times, factors such as breastfeeding can be impacted by sibling competition.

Jealousy in Childhood and Early Adolescence

Similar to infancy, children and adolescents compete with their siblings for parental investment. In ancestral environments, resources were scarce, and so parental investment in one child could have posed a threat to the survival of another (Hart 2010). Thus, if a mother were to pay more attention to one child, it would be adaptive for a sibling

to redirect her attention to oneself. Jealousy would evoke behavioral displays to meet the goal of regaining the attention of the primary caregiver in order to secure the resources needed to promote survival (Hart 2010). In childhood, attaining more resources for oneself by means of competition contributes to survival and eventual reproductive success (Weisfeld and Woodward 2004).

Research on jealousy in early and mid-childhood is also limited. Many studies focus on negative features of the sibling relationship, such as conflict or aggression, which may be the consequence of jealousy, but this distinction is not clear (Volling et al. 2010). Many studies on childhood jealousy are observational, where jealousy is inferred from actions. For example, Volling et al. (2010) examined displays of jealousy in siblings ages 4–6 and in toddlers at age 2 by manipulating how much time parents had with both the toddler and the child, alternating direct interaction and attention to one child for three minutes (involved condition) while the other child was encouraged to go play independently (challenged condition). They found that both the toddler and the child exhibited significantly more negative affect and less positive affect when in the challenged condition in both the sibling-mother and sibling-father trials. Toddlers were found to exhibit two types of behavior, interference and seeking comfort, when in the challenged condition. Older children exhibited these same behaviors and attention seeking. Volling et al. (2010) suggested that attention seeking is more sophisticated at distracting parents than physically pushing oneself between the parent and rival sibling, as a toddler would do. As children get older, jealousy is still a response to a “rival” sibling, but methods of regaining attention to oneself become more refined and effective.

In addition to sibling jealousy, children exhibit jealousy in the context of friendships (see Dillon 2013, for a more exhaustive review). Jealousy is observed when a friend interacts positively with another child, or when there are perceived inequalities within the friendship, leading to behaviors to regain the favor of the friend or ultimately terminate the friendship. Parker et al. (2010) posited that jealousy may arise because the

actions of the friend infer that the person is not socially desirable and is being rejected by the “unfaithful” friend. Sex differences in relationship jealousy have been identified. Girls are more prone to friendship jealousy, presumably because girls tend to have fewer, more intimate friendships, and boys tend to establish a social hierarchy in the context of a larger peer group.

In early to mid-adolescence, sexual competition emerges due to sexual maturity. Individuals with a higher social status have more reproductive success, and so achieving and maintaining this status is important. de Bruyn et al. (2012) found that sexually precocious middle adolescents were more popular, attractive, and aggressive. A threat to an individual’s social status by a rival could evoke jealousy, a possible driving force behind physical aggression among male and relational aggression among female adolescents. By showing off their strength and dominance through behaviors such as bullying, adolescent boys could intimidate their rivals and reduce the rival’s reproductive success. Adolescent females have more of a tendency to lower a rival’s status through use of relational aggression and hurting the reputation of rivals, thus decreasing their reproductive success (de Bruyn et al. 2012). This study does not examine jealousy specifically; however, there is recognition that an individual perceiving a threat from a rival elicits behaviors that decrease the status of a rival, and increase the individual’s reputation and appearance of being reproductively superior.

Jealousy in Late Adolescence and Adulthood

In late adolescence into adulthood, the function of jealousy increasingly changes from protecting parental and peer attention and resources to guarding one’s own reproductive success (Dillon 2013). Research on early to mid-adulthood jealousy has been more prolific. Displays of sexual and emotional jealousy are more pronounced during early to mid-adulthood because of its function of alerting one to the threat of a mating rival. There is competition in both attaining and then

retaining a desired mate, as well as ensuring fidelity. In humans, adulthood typically marks a period of establishing long-term mateships and cooperatively raising offspring. Sexual jealousy in this context exists when there are potential threats to extra-pair mating. Sexual jealousy alerts an individual to the presence of an interloper and triggers the use of tactics to secure or maintain sexual exclusivity with a partner.

An evolutionary framework posits that there are sex differences in jealousy due to different types of infidelity uniquely impacting male and female reproductive fitness (Sagarin et al. 2003). When alerted to the threat of a rival, males are likely to be more jealous of sexual infidelity, due to risks of paternity uncertainty, leading to potential investment of resources into someone else's offspring (i.e., cuckoldry risk). Conversely, females are likely to experience more jealousy around emotional infidelity because emotional investment in a rival female could lead to resources being diverted from her offspring to the offspring of a rival (Sagarin et al. 2003).

Shackelford et al. (2004) proposed that one way to look at the effect of age on jealousy was to determine if sex differences in jealousy from a young sample of young adults are also found in older adult samples. When female partners reach menopause, sexual infidelity no longer poses cuckoldry risk to the male, suggesting there should not be as large of a sex differences in sexual jealousy. For older women with children in adulthood, the effect of emotional infidelity would not be as significant because resources for dependent children are no longer needed. Shackelford confirmed sex differences were still found in the older sample of older adults, but that the magnitude of the difference decreased. Interestingly, older women were less likely to choose a partner's emotional infidelity as more upsetting than sexual infidelity, contrary to younger women.

Jealousy in the context of a romantic relationship can be detrimental because it evokes negative feelings of anger, fear, and sadness. However, it can also be argued that experiencing jealousy can enhance commitment to a relationship, and so inducing jealousy can help to achieve relationship goals (Wade and Weinstein

2011). By fostering doubt regarding one's commitment to their partner, jealousy can be induced to help preserve the existing bond and fend off interlopers.

Jealousy in Late Adulthood

Research on the incidence and function of jealousy in late adulthood is limited, and so firm conclusions cannot be made. Some studies are now examining jealousy in late adulthood in terms of delusional jealousy associated with neuropathological disorders such as dementia (Hashimoto et al. 2015; Cipriani et al. 2012). Future research will need to control for the effects of neurological or mental health deterioration on jealousy.

Conclusion

Across the lifespan, jealousy serves as an important indicator of a threat to significant social relationships, prompting behaviors to divert a valued party's attention from a rival and back to oneself in order to maintain ongoing benefit from the relationship.

At the earliest stage of life, it is difficult if not impossible to determine if infants are experiencing jealousy or even capable of that specific emotion. However, observational research has repeatedly found that infants engage in behaviors to gain the attention of their caregivers when it is diverted to a sibling or another social threat. This suggests that jealousy may exist as one of human's earliest emotions, functioning as the emotional trigger to retain the attention of a caregiver.

As children age and become more independent, they still largely rely on parents to assist with their growth and survival. When parental attention is diverted to a rival sibling, efforts to regain the attention are triggered by feelings of jealousy. In this sense, jealousy functions in quite the same way as in infancy, but an older child's methods to gain and retain the attention of a caregiver become more sophisticated.

In later childhood and early adolescence, the function of jealousy appears to expand from the protection of caregiver attention for survival to also include the promotion of oneself as socially desirable. Jealousy again appears to be the alert of a threatening third party, but the threat is to a significant social relationship that is adding to the social status of the individual. Social desirability becomes more important in adolescence because reproductive success is contingent on social status. It can be argued that jealousy is the emotion that evokes the behaviors that attempt to diminish a rival's social status while strengthening one's own. Sex-specific forms of jealousy start to emerge at this age.

Once long-term relationships are pursued or established, typically in adulthood, jealousy's function is primarily to alert an individual about the threat of an interloper. For a male, the threat of sexual infidelity evokes more jealousy due to cuckoldry risk, whereas for females, jealousy is more prevalent when the threat of emotional infidelity is present. This is likely due to a female's reliance on the male for time and resources to contribute to their offspring, which could be diverted to the rival's offspring if the male was emotionally involved. Maintaining a partner's fidelity is reproductively important for both sexes throughout adulthood.

In later adulthood, a sex difference generally still exists but the magnitude of the difference decreases. Men still find sexual infidelity as more upsetting than emotional infidelity, but one difference is that post-menopausal females experience sexual infidelity as more threatening than emotional infidelity. The higher distress level in older women around sexual infidelity could be in response to the fact that their male partner is still able to reproduce and could do so with a woman with higher mate value. It would be interesting to see if an older woman's degree of jealousy around emotional versus sexual infidelity would differ depending on the perceived mate value and/or fertility of the threatening woman. Sexual infidelity with a younger female could be more threatening than emotional infidelity because pregnancy could lead to relationship defection and investment of resources in the new partner.

If the threat was from an older, postmenopausal woman no longer able to reproduce, perhaps emotional infidelity would still be perceived as more threatening. This could help to clarify if it is the age of the woman that is the source of jealousy or if it is the reproductive viability of the threat. More research on the function of jealousy in late adulthood is needed, controlling for the possible effects of organic brain disorders.

Jealousy: Psychiatric Diagnosis

Conjugal paranoia; Delusional disorder - jealous type; Morbid jealousy; Pathological jealousy; Othello syndrome

Introduction

Jealousy refers to an emotional response that emerges when an interpersonal relationship is impacted by another person. Jealousy is functional because it alerts individuals to the presence of a rival and motivates behavioral responses to minimize the impact of a rival on valued interpersonal relationships. For example, people become

jealous in response to partner infidelity, new members of social relationships, and parent-sibling interactions. However, some people experience jealousy in the absence of a threat or rival and maintain such beliefs even in the presence of disconfirming evidence (Cipriani et al. 2012). In these cases, jealousy is no longer functional because it can lead to expending energy and resources fending off a rival that does not exist (Kingham and Gordon 2004). In the context of intimate relationships, when jealousy is not based on a real threat and is persistent despite contrary evidence, it is known as *delusional jealousy* (similar constructs include *pathological jealousy*, *Othello syndrome*, *morbid jealousy*, *conjugal paranoia*) and is applied to sexual jealousy. There are no psychiatric disorders that encompass pathological jealousy between siblings, friends, or other non-intimate social relationships. A person afflicted with delusional jealousy interprets their partner's actions based on how they feel, and irrational thoughts about their assumptions being true initiates even more fear, rage, and insecurity (Seeman 2016). This form of jealousy may be characterized by an individual making unfounded accusations to their partner, demanding reassurances, wanting to know the thoughts of their partner, or spying (Seeman 2016).

Delusional jealousy is characterized by a range of irrational thoughts and extreme behavior in response to the belief that one's partner is being sexually unfaithful (Kingham and Gordon 2004) without reasonable or objective evidence (Easton et al. 2008). These individuals will continue to insist on the occurrence of infidelity, even if evidence to the contrary is presented (Kingham and Gordon 2004).

Delusional Disorder-Jealous Type

Delusional jealousy is not classified as a stand-alone disorder and is often considered a syndrome rather than a diagnosis (Kingham and Gordon 2004). A clinical diagnosis relevant to sexual jealousy is in the Diagnostic and Statistical Manual (DSM-5; American Psychiatric Association 2013) which includes diagnostic criteria for delusional

disorder-jealous type. The current criteria for delusional disorder includes: (1) having one or more delusions over the course of a month or longer; (2) does not meet criteria for schizophrenia; (3) a person is not necessarily severely impaired or oddly behaved; (4) if person also presents mania or depression, their duration must be less than the duration of delusions; (5) symptoms are not due to other physiological issues or use of substances and cannot be better explained by another diagnosis. In addition to the general diagnosis, the DSM-5 (APA 2013) uses specifiers to identify the central theme of the delusions being experienced. These include Erotomantic type, Grandiose type, Jealous type, Persecutory type, and Somatic type, Mixed type, or Unspecified type. Diagnoses also specify if there is bizarre content, and after a year's duration of the disorder, the number of episodes a person has experienced must be identified, in addition to the current state of their episode (acute, in partial remission, or in full remission). While not necessary for diagnosis, there is also a severity specifier to note the frequency of symptoms (APA 2013).

The subtype of delusional disorder, *jealous type* is applied when the central theme of an individual's delusion is that his or her spouse or lover is unfaithful. The belief of infidelity is without due cause, based on incorrect interpretations of small bits of evidence. The delusional individual often confronts the partner and attempts to intervene in the imagined infidelity (APA 2013). A problem with the DSM-5 criteria regarding sexual jealousy pathology is an over-emphasis on delusions, which does not account for other types of sexual jealousy such as Othello syndrome, morbid jealousy, or conjugal paranoia. This lack of differentiation leaves it unclear if these represent different types of sexual jealousy or if they are part of a broader category of jealousy-related disorders (Easton et al. 2008).

Prevalence of Delusional Disorder-Jealous Type

Delusional disorder-jealous type is considered the "purest" diagnosis of delusional jealousy,

because it is not accompanied by additional psychopathology (Kingham and Gordon 2004). The APA (2013) estimates that the lifetime prevalence of delusional disorder is about 0.02%; however, the estimated prevalence of jealous type specifically is not noted.

Easton et al. (2008) studied case histories that included delusional jealousy and alternative titles that are often used to indicate the same disorder (morbid jealousy, pathological jealousy, conjugal paranoia, and Othello syndrome). All 398 case histories reviewed included some form of morbid jealousy, and 283 of these experienced delusions around partner infidelity for over 1 month. This is the first and most relevant DSM diagnostic criterion for delusional disorder-jealous type. Easton et al. (2008) identified the frequencies of the cases that matched each individual DSM-IV-TR diagnostic criteria for delusional disorder-jealous type, and then ultimately the frequency of cases that met all five of the criteria among psychiatric patients with delusional jealousy. Of the 398 case histories, it was determined only 16 (4%) of cases met all five DSM-IV-TR diagnostic criteria and were thus determined to have delusional disorder-jealousy type (Easton et al. 2008).

The Easton et al. (2008) study elucidates an important point, that individuals who experience delusional jealousy can meet some of the criteria of delusional disorder-jealous type but not enough to earn the diagnosis. Also, considering that only 4% of the jealousy-pathology cases reviewed met all criteria for delusional disorder-jealous type, it is possible that the current criteria are not inclusive enough to capture other jealousy pathologies (Easton et al. 2008).

Soyka and Schmidt (2011) analyzed case histories from 2000–2008 at a psychiatric inpatient facility in Germany. Seventy-two of 14,309 case histories were found to have delusional jealousy, with delusional disorders accounting for 11.1% of these cases specifically (Soyka and Schmidt 2011). This study did not separate delusional disorder-jealous type from other typologies, thus the relative frequency cannot be determined. The case histories analyzed in this study all had psychiatric diagnoses, so in the other 88.9% of cases,

delusional jealousy was attributed to another mental disorder (Soyka and Schmidt 2011).

Other DSM-5 Diagnoses

In the DSM-5, there are psychiatric diagnoses that are comorbid with jealousy. Depression can accompany delusions of infidelity that stem from feeling inadequate in the context of a romantic relationship, though it is unclear if the depression leads to the delusions or is a result of them (Kingham and Gordon 2004). In Easton's (2008) sample which had some form of pathological jealousy, 309 of the 398 cases reviewed were determined to have some type of psychological disorder, 40 (12.9%) of which were diagnosed with depression, making it the second most common psychological disorder in which pathological jealousy was present. The case analysis conducted by Soyka and Schmidt (2011) did not examine depression specifically but found that mood disorders (as diagnosed by the ICD-10) accounted for 19.4% of cases identified as having delusional jealousy. To distinguish the cause of delusions in these cases, it is important to review the chronology of the mood disturbance, the delusions, and the severity of mood symptoms (APA 2013). If delusions are only present in a depressive or bipolar disorder during a mood episode, the primary diagnosis would be that particular mood disorder (i.e., "bipolar disorder psychotic features" would be added as a specifier to explain delusional jealousy as being present during an episode; APA 2013).

Soyka and Schmidt (2011) found that the highest prevalence of delusional jealousy occurred in patients diagnosed with a psychotic disorder, and Easton et al. (2008) found that 27 of 309 cases with delusional jealousy also had an official diagnosis of schizophrenia/paranoid schizophrenia. Delusions of infidelity may arise as a component of schizophrenia, in the form of persecutory delusions experienced during psychosis (Kingham and Gordon 2004). However, the bizarre associations that are characteristic of schizophrenia are not necessarily focused on sexual infidelity, and these individuals experience other unrelated symptoms of

psychosis. Individuals with delusional disorder-jealous type do not describe bizarre associations, but coherent descriptions of plausible situations in which their partner is being unfaithful (Kingham and Gordon 2004). The DSM-5 confirms that individuals diagnosed with delusional disorder will not exhibit symptoms characteristic of schizophrenia, such as "prominent auditory or visual hallucinations, disorganized speech, grossly disorganized or catatonic behavior, or negative symptoms" (p. 104).

Organic brain disorders can also lead to delusional jealousy. In fact, delusional jealousy has been found to occur most frequently in patients with neurological disorders (Graff-Radford et al. 2012). At least 30% of cases with a delusion of infidelity can be linked to some form of neurological condition (Cipriani et al. 2012). For example, delusional jealousy is not uncommon in different forms of dementia, such as Alzheimer's disease (Tsai et al. 1997; Cipriani et al. 2012).

In their analysis of clinical and imaging features, Graff-Radford et al. (2012) found that of the 105 patients that met criteria delusional jealousy, 73 met criteria for a neurological disorder. Neurodegenerative disorders accounted for 76.7% of these neurological disorders, most commonly Alzheimer's disease, Lewy body disease, and a behavioral variant of frontotemporal dementia (Graff-Radford et al. 2012). Compared to matched neurodegenerative patients without delusional jealousy, those with it exhibited greater grey matter loss predominantly in the dorsolateral frontal lobes of the brain. Graff-Radford et al.'s (2012) main finding was that delusional jealousy is found in a variety disorders often related to frontal lobe dysfunction and/or damage.

An individual with a neurocognitive disorder may present with the same symptoms identified in delusional disorder-jealous type. As with mood disorders, it is important to review the chronology of the onset or exacerbation of delusional jealousy to see if it parallels the course of the neurological disorder or damage to the brain. If it does, the associated DSM-5 diagnosis would be a neurocognitive disorder, with delusional jealousy as a result of this disorder (APA 2013).

Similarly, an individual with substance or medication induced psychotic disorder could meet the

criteria for delusional disorder. In reviewing the timeline of substance use and onset and remission of the delusions, the substance can be considered or ruled out as the cause (APA 2013). For example, dopaminergic medications used to treat Parkinson's disease have been linked to delusional jealousy (Poletti et al. 2012). Graff-Radford et al. (2012) found that individuals who had Parkinson's disease without dementia exhibited delusional jealousy after an increase in dopamine agonist medication. When the medication was reduced or stopped, the delusions dissipated. They found a similar trend with patients who were treated with stimulant medications, which also affect dopamine (Graff-Radford et al. 2012).

Conclusion

Delusional jealousy is not currently recognized as a stand-alone diagnosis, even in the most recent version of the DSM (APA 2013). While Delusional disorder-jealous type does capture the presentation of delusional jealousy, the exclusion criteria for this specific disorder leave many instances of pathological jealousy unidentified. Perhaps if delusional jealousy were an independent disorder, it could be categorized into typologies by its relation to different disorders (i.e., delusional jealousy, resulting from active mood disorder). This way, if delusional jealousy were a prevalent psychological condition, it could be clinically identified and given more specific attention in the context of treatment. The identification of delusional jealousy could also be the presenting symptom that may lead to the identification of treatable underlying conditions such as disorders of mood, psychosis, and neurology. It also could inform the treatment of such underlying disorders, perhaps alerting providers to find alternatives to medications that are dopaminergic in nature or using an antipsychotic medication to counter its effects.

Evolution theory; Lamarckism; Philosophie Zoologique; Theory of the descent; Transmutations theory

Definition

The French naturalist Jean-Baptiste Lamarck is one of the most representative figures of modern biology in the nineteenth century. Botanist and zoologist, he was a great systematic taxonomist establishing the current division of the animal kingdom in invertebrates and vertebrates. He also defined the term biology with its modern sense as a set of vital processes. And he was, above all, the first to use the idea of evolution to explain the history of life. His well-known book *Philosophie Zoologique* gathers his way of thinking about evolution. He is, together with Charles Darwin and Gregor Mendel, one of the key elements to understand the formulation and subsequent development of the theory of evolution.

Introduction

Nature is for mankind a collection of surprising beings and occurrences. Discovering which objects comprise it, observing its phenomena, and determining its laws are endless – perhaps interminable – tasks. The desire for knowledge arises in the minds of men trapped by necessity, curiosity, and vanity. Under this scenario, scientists have applied two master formulas to represent it. First is the fixism model, representing a closed, timeless system. A snapshot of beings who eternally are born, grow, reproduce, and die. Then there is the contemporary theory of evolution with its changing and perishable world. The application of one scheme or the other depends on the significance attributed to fossil remains. Leonardo da Vinci and Bernard Palissy, for example, both understood their value as living matter. However, until 1600, there was complicity to consider them as artifacts unconnected to life. Afterwards, naturalists started to abandon speculation by experimentally testing their organic condition. In the following century, another twist on the theme occurred when extinction was accepted as a phenomenon of life. As a result, species known from their remains were recognized to have inhabited Earth in the past. This

theory of lost species divides the natural system into two existential categories: geological time and biological time. The universal and the particular.

The botanist Carl Linnaeus promoted the temporal idea. In *Disquisitio de Sexu Plantarum* (1760), his explanation of organic diversity as a biological process is a pre-evolutionary theory scientific approach. Linnaeus considers hybridization as a phenomenon capable of producing new plants, and, in this way, they diversify over time. Creation is limited to the origin. Nature then acts alone. His hybridization model is a restrictive, regulated application of the fixism theory. God is the creator, but the act has lost its supernatural condition, becoming an actualist, reproductive process.

Around the same time, the celebrated naturalist Count Buffon proposes a more ambitious, complex, and refined version of this fickle nature. According to his *Les Époques de la Nature* (1778), Earth's history consists of seven stages. The first and second stages are abiotic and form the conditions necessary for life, which bursts through during the third stage. The first animals are aquatic. They would also be the first victims, the first species to be lost when the environment changes. The fourth stage is the era of the plants. In the fifth, a green carpet awaits the arrival of the gigantic animals known from their fossilized remains. It is also the time of uncivilized humans. The current continental division occurs during the sixth stage, and, in the last, man takes possession of the Earth. The big question is: How does life emerge from inanimate matter? In the theory of organic molecules – a fantastic hypothesis – organisms are formed through the aggregation of indestructible living particles, formed by the heat that acts on the malleable material. After species become extinct, the molecules are released to organize themselves in different ways into other species. Buffon develops a materialist concept of life but without a biological nexus, far from any notion of common descent. The idea of organizing nature through a philological law appears in other texts of his well-known *Histoire Naturelle*, suggesting its possible interpretation as an evolutionary event. The first step towards

evolution had been taken. It consisted of replacing creation with a self-sufficient world. It was under this context that Lamarck, from 1800, would reveal his transmutationist ideology and propose a different way to think about nature as a demystified entity, reduced to physical processes and composed of species with a common origin. Lamarck changed the analytical scene by converting organic function into the true reference of living beings. The science of biology was born.

The Chevalier de Lamarck

Jean-Baptiste Pierre Antoine de Monet, Chevalier de Lamarck, was born on Saturday, the 1st of August 1744, in Bazentin, a small town in northern France. He was the 11th child of Philippe de Monet, a knight of Saint-Louis and commander of the Château de Dinan. It was noble family with military roots whose prominence had been in slow decline for the last 300 years. Too many brothers and a diminished heritage led Lamarck to a seminary run by Jesuit fathers in the city of Amiens. It was the start of his ecclesiastical career, during which he earned the nickname the *petit abbé*. After his father's death, at the age of 16, Lamarck replaces the *Bible* with the saber. Looking to enlist in the *Beaujolais* regiment, which was waging war on the northern border, he was admitted as a volunteer. In July 1761, he participates in the Battle of Villinghausen, a well-known episode of the Seven Years' War, in which the French troops suffer a bitter defeat. Lamarck, however, is appointed an officer for his heroism, though he would leave the army as abruptly as he joined it. After the war, in 1763, the regiment is stationed in Toulon and then in Monaco, where he suffers a serious injury. He spent over a year convalescing in Paris: a time to read and meditate, to learn botany and meteorology, and to understand that he could progress in life without losing it. He left the army and entered medical school. Hard times. He worked to survive, combining his studies with his job as a banker. But Lamarck was not born to be a doctor. After 4 years, botany replaced medicine. In 1778, he writes *Flore Française*: an effective methodological treatise to recognize the

name of plants using easy dichotomous rules. The work was a success, earning the favor of the powerful Count Buffon who had it printed with the stamp of the royal printing house. Between 1781 and 1782, Lamarck travels throughout the territories of Germany, Austria, Hungary, and Holland, accompanying the count's son as his tutor – a task that earned him an appointment as a royal botanist. Upon his return, he would manage the botanical section of the famous *Encyclopédie Méthodique*. In 1788, thanks to Marquis de Billarderie, manager of the Jardin des Plantes, the King's Garden, he is appointed as curator of the Royal Cabinet's herbariums. He was in charge of fixing and organizing them, which earned him a salary of 1,000 francs. In 1793, he becomes chair of the invertebrate department at the French National Museum of Natural History. No professor wanted the post. His knowledge of “white-blooded” animals, as they were called at the time, was scarce. They were a group forgotten by nearly everyone. Land, aquatic, and underground animals. Walkers, flyers, swimmers, jumpers, and crawlers. Thousands of species: some 135,000 were known at the time compared to the around 10,000 known of the other groups. Lamarck knew how to order the chaos. He separated crustaceans from insects, defined arachnids, distinguished annelids among the worms, differentiated the echinoderms from the polyps, and, fundamentally, had the intelligence, intuition, and success to call them animals without vertebrae. The animal kingdom was divided into two universally accepted groups, vertebrates and invertebrates, as he explains it in his book *Système des Animaux sans vertèbres* (1801). Professor Lamarck remained faithful to the museum until his death on the 18th of December 1829. He even turned down a position as chair of zoology at the Faculty of Sciences. Nearly 30 years in which life and work were intertwined. Three decades also represented by works such as *Hydrogéologie*, *Recherches sur l'organisation des corps vivans*, *Histoire naturelle des animaux sans vertèbres*, *Système analytique des connaissances positives de l'homme*, and, particularly, *Philosophie Zoologique* (Lamarck 1802a, 1820). Lamarck is a man of revolution. He wrote books for a

magnanimous and victorious people. He wants to be useful to his fellow man, to his brothers, and to his peers, as evident in the printed dedication of *Recherches sur les causes des principaux faits physiques*. A committed citizen, he was not in tune with the Napoleonic era. Neither the empire nor the restoration fit him well. Many scientific institutions welcomed him with open arms. He trained, in part, at the Institute of France, the Parisian Philosophical Society, the French Royal Academy of Sciences, the Moscow Society of Naturalists, the Royal Academy of Sciences of Munich, the Berlin Society of Friends of Natural Science, the Strasbourg Society of Agriculture, and the Agricultural Society of Lyon, among others. The twilight of his life was sad and difficult. He fell upon hard times. He buried three wives and several of his eight children. To scrape by, he sold his library, his herbarium, and all of his collections. He died blind and poor. His body was buried in a mass grave in the Parisian cemetery of Montparnasse. Life did not do him justice. History also does not, conceding him a secondary role in the cast of the historical blockbuster entitled *Evolution*. However, it was Lamarck who courageously used the evolutionary idea to explain the history of terrestrial life (Simpson 1953). What were the terms of the proposal?

A New Philosophy on Life

The philosopher Henri Bergson explained his interest in organic evolution at the Huxley Conference of 1911 (Bergson 1919). Briefly, species are generated from other, simpler ones. A hypothesis confirmed by comparative anatomy, embryology, and paleontology since the time of Lamarck and Darwin. In his testimony, we recognize two foundational arguments of the evolutionary theory. First is the general nature of the phenomenon to generate new species by modifying existing ones. It is a descriptive argument, the “what is happening,” from which the different theories develop their own explanations for how and why it happens. Second is the empirical condition of the theory based on data contributed by different disciplines. These two arguments form

the general ideological framework of the theory, as outlined by Lamarck and maintained by successive evolutionary models. In Yves Delage’s view (1895), before Lamarck, it was unthinkable to attribute a natural cause to the origin of species. Or more precisely, the impossible was not to think of life in physical, chemical, or biological terms. It was to close the circle and to explain the genesis of living beings by their genealogy, relating them to each other and to the environment. The impossible was to define a sequence of continuous biological information from the past to the present through reproduction. Lamarck’s wisdom is epistemological: it consists of giving nature a new status, renewing the classical concept of the *scala naturae* or the great chain of beings – a scheme, since Plato and Aristotle, that related organic forms by their morphological proximity to comprise a rectilinear sequence of increasing complexity and perfection up to the human race. Living beings represented a unique, unilateral, one-dimensional, and unidirectional natural group. For Lamarck, nature represents a well-organized group but one not related to the *scala naturae*. In 1800, he publically rejects the concept and abandons the uniformity. He does not interpret it as a regular, linear series but rather a sequence limited to the organizational system of classes and major taxonomic families, a common trunk from which species emerged as lateral branches. It is a new treelike symbolism of the natural order, initially bifurcating into the animal and plant kingdoms that later develop through continuous phyletic series. Nature is composed of living beings grouped into species whose persistence is relative. They are only temporarily invariable. The individual is the essence of the whole, the circumstance that defines and maintains it.

In 1802, during the opening of the zoology course at the natural history museum, Lamarck explained that he had long accepted the principle of species invariability. It was an error that he would not repeat. Reformulating the concept of species was a consequence of observing nature from an evolutionary perspective. Now, a species would be a collection of similar individuals over a long period of time with the exception of small,

accidental differences. Then, after an implausible amount of time for human existence had passed, environmental conditions gradually change, and individuals adjust their topology to accommodate their new needs. They acquire another conformation that is inherited by their descendants. The group now constitutes a different, equally perishable species. A subgroup could also become accidentally separated from the collective and experience different environmental conditions elsewhere. Lamarck hypothesizes that it would develop new habits to survive and thus form another species, thereby incorporating a mode of speciation by geographical isolation into the evolutionary process. A future look to evolutionary biology of the twentieth century. Species, therefore, are not a product of Linnaean time but rather of the environment, and adaptation would be the evolutionary causation – a necessary condition for the survival of individuals. In this context, the phenomenon of extinction is meaningless since there is no existential interruption in individuals, just a continuous adaptive conversion. Indeed, fossils do not identify lost species but rather only show what they were like before the change in form. They are expired pieces of a process of nonselective substitution, because there is not intraspecific neither interspecific competition.

Lamarck, in his outline of his biological theory on the origin and the development of life, emphasizes organic instability as a quality of nature. But if the hypothesis, in general, culminates with the idea of an independent nature that is capable of achieving such achievements on its own, the underlying message is a sea of doubts about the truth of nature as it was then known. The remedy for such ignorance would be an innovative research program. A naturalist would have to be ambitious and not just spend time and effort on describing and classifying. To identify an object is not enough to know it. It is necessary to discover how nature forms and renews its output. The priority would be to analyze the set of relationships that allows a living organism to be expressed as an anatomical-functional model. The idea is to know its organization by studying what phenomena occurred during reproduction and

development and to relate the effects of environmental conditions and lifestyle on the body. This is the biological significance of Lamarck's *Philosophie Zoologique*. A work on the principles of animal life written in order to determine what life is and what conditions are necessary for it to manifest itself. The general conclusion is that, to survive, an individual undergoes adaptive transformations in response to the environment. Adaptation, phyletic continuity, and chronological variation are the foundational pillars of the Lamarckian evolutionary archetype (Galera 2009). The formula has since then travelled through time generating an intense, controversial, and unending debate on the origin and transient nature of species. Because it is one thing to be an evolutionist but another to explain the how and the why of evolution (Simpson 1951). Thus, far from falling into oblivion, Lamarckian thought is today considered an asset of the evolutionary theory because his transformist vision of nature, imbued with knowledge, comprises a bouquet of possibilities not previously considered. It is not so much for his well-known hypothesis on the inheritance of acquired characteristics itself but its understanding that habits can guide future evolution.

In the 50 years that passed from the first appearance of *Philosophie Zoologique* to the first edition of the *Origin of Species*, Lamarck's transmutationist ideology certainly circulated the academic circles. He had supporters and detractors (Galera 2017). Charles Darwin himself acknowledges that he had reached similar conclusions, as he relays in a letter dated 11 January 1844 to the botanist Joseph Hooker. His testimony underlines a consensus with Lamarck to define life as a process of adaptive substitution. The difference essentially lies in the proposed mechanism, in the adaptive model, and in the determination of whether the cause is teleological or random. However, historians often underestimate the figure and the ideology of Lamarck by using a categorical argument: evolution only makes sense in light of Darwinism. Is this true? To address this question, we analyze the role of Lamarckian ideology within the scientific community prior to the publication of the *Origin of Species*.

The Transmutation of Species Doctrine

From 1800 on, Lamarck explains his *theory of the descent*, as it was also known, to his zoology classes. It is immortalized in his book *Philosophie Zoologique* (1809), although it emerged earlier in treatises such as *Système des animaux sans vertèbres* (1801) and *Recherches sur l'organisation des corps vivans* (1802b). The building of his transformist idea of nature continues in *Histoire naturelle des animaux sans vertèbres* (1815–1822). In 1830, *Philosophie Zoologique* is reissued, but it would be another 40 years before a new edition is published in 1873 by Charles Martins, director of the Botanical Garden of Montpellier. By then, Lamarck had already passed away. In Britain, the Lamarck's *Philosophie* was available relatively quickly. In the October 1811 issue, *The Monthly Magazine* communicated to readers the possibility of buying the book. That same year, the literary journal *The Monthly Review* published an extensive review explaining its content – continued in 1813. A brief informative note published in *The New Annual Register*, 1812, recalled the naturalistic interest of the work and the convenience of translating it to English. However, it was not translated until 1914. Previously, the journal *The American Naturalist* in its 1888 issue included the translation to English of the seventh chapter of the first volume. No doubt. The limited editorial projection of the book impaired its dissemination. So, what scientific impact did his theory have?

In 1813, renowned Swiss botanist Augustin Pyrame de Candolle showed his opposition to the theory of the *non-permanence of species* in his book *Théorie élémentaire de la botanique*. His rejection has a taxonomic sense, defending the constancy of species as a basic systematic condition. In his mind, nature is permanently ordered, and only those characteristics that do not change the identity of a group are modifiable. The slow and gradual change of species proposed by the theory of transmutation was an unacceptable idea that violated the general principles, and to attribute the morphology of beings to their habits was an absurd hypothesis. Another case. The year is 1817. For the

German philosopher Friedrich Hegel, as he expresses in *Enzyklopaedie der philosophischen Wissenschaften im Grundrisse*, the unique vision of a changeable nature was but one of those nebulous, sensitive, and ineffable representations that the human intellect should reject. To attribute a material origin to life and to conspire a fickle, inconstant, uncertain, incoherent world was simply an outlandish notion. That same year, in the prologue of the third English edition of Georges Cuvier's *Essay on the Theory of the Earth*, the Scottish geologist Robert Jameson expresses a different view (Cuvier 1817). Jameson identifies two sides: the paleontologist Cuvier leading the anti-transformist camp and Lamarck carrying the evolutionist banner by interpreting nature as an unstable group of living beings subjected to the modifying action of the environment.

The Reverend John Fleming, a famous Scottish botanist, geologist, and zoologist, knew of and rejected the theory of transmutation, as evident in his *The Philosophy of Zoology* (1822). True, the geological strata contain remnants of extinct plants and animals that, to some extent, differ from current species, with those most similar being found in the most recent deposits. This stratigraphic sequence was the relatedness argument used to support the common descent of modern flora and fauna by environmental causes. Fleming arbitrarily rejected the idea. Life simply has limits, and the transmutation of species was one. “It never happened,” he declares, foreshadowing the arduous task proponents of the theory would have to face to prove it. He was right, at least in pointing out the difficulty of the task. He wrote no names, but the Lamarckian connection is discernible in both the modus operandi and the reference to the first volume of *Histoire naturelle des animaux sans vertèbres*. More testimonies. In 1826, the *Edinburgh New Philosophical Journal* published “Observation on the nature and importance of geology” by Professor Robert Edmond Grant, historically known for his professorial relationship with Darwin. The question of the origin of living beings was one of his concerns. His favorite response was the unequivocal theory of “Mr Lamarck.” The organic world originated from simple animals,

such as infusorians, by spontaneous generation. The others gradually had evolved, driven by external circumstances – a hypothesis supported by the *doctrine of petrification*.

In *Éléments de géologie*, published in 1831, the Belgian geologist Jean-Baptiste d’Omalius explains that the most plausible hypothesis to justify the concatenation of species occurred during the world’s geological history, the reproductive substitution of ones for others caused by external circumstances. Even Charles Lyell was surprised to find that his colleague had opted for the Lamarckian system of transmutation. A year later, Lyell made his position clear in the second volume of *Principles of Geology* in which he uses the term *evolution* to refer to the Lamarckian concept of a chronologically modifiable nature that is linked to a space – an ideology that he rejected until the 1860s (Lyell 1830–33). The volume faithfully reflects the contents of *Philosophie Zoologique*. It is, in fact, its first attestation in the English language. In Lyell’s rebuttal, there is a hesitant tone against a hypothesis that had internal logic and consistency and that might not have been wrong. It was Lamarck who revealed the theory of evolution to him in anticipation of Darwin.

In 1833, parish priest William Kirby, a prestigious English entomologist who was considered the founding father of the discipline, published the seventh volume of the *Bridgewater Treatises*, a famous collection on natural theology. It was entitled *On the Power, Wisdom and Goodness of God as Manifested in the Creation of Animals and in Their History, Habits and Instincts*. Kirby had clear ideas. Addressing the theme of God and nature, he would not forget Laplace and Lamarck, two of the most eminent philosophers of the century. A physicist and a zoologist who ignored God by attributing Creation to secondary causes. Lamarck’s great error was his steadfast materialism leading to an irrational, inanimate nature, composed of laws and parts that do not go beyond their sensations. Nature transformed into a *genealogical tree* based on a microscopic organism indifferent to reason. Kirby knows the biological significance of the theory. Heat, electricity, and physical attraction penetrate inorganic matter,

producing excitability and life – cellular tissue. Components that will give rise to primitive beings capable of reproducing by splitting and budding. Then, life made a virtue of necessity. The stimulus to feed formed the mouth; the digestive capacity fostered the stomach and intestines. And so on, moving towards the complexity and diversity of living beings. He believes that nothing new could be added to Lyell’s works to demonstrate the stability of nature. In another volume of the *Bridgewater Treatises* entitled *Geology and mineralogy* (1836), the Reverend William Buckland, renowned geologist and paleontologist, reveals his view of Lamarck as an anti-creationist enemy. He does not hesitate to inform the reader of the ideological danger of a doctrine that excludes the Creator by explaining the origin of species through development and transmutation.

More arguments. The influential British philosopher William Whewell, in the third volume of his *History of the inductive sciences* (1837), explains that the controversy between supporters and opponents of the *doctrine of the transmutation of species* was one of the most outstanding issues of the scientific debate. Geologists and paleontologists had shown that different groups of animals and plants inhabited the Earth successively. It was a scientific fact. The dilemma was to accept the doctrine of transmutation – species of a geological age transforming into other forms due to natural causes – or to acknowledge the miracle of successive creation of species after the extinction of previous ones. The philosopher picked the latter option. Whewell maintained his opinion in the revised edition of 1847. When writing the third volume of *Cours de philosophie positive* (1838), Auguste Comte did not forget the Lamarckian transformist discussion. The theory was a philosophical problem against the method – against the natural method and the immutable hierarchical order. The relationship between the environment and morphological variation were indisputable principles, but, poorly applied, they formed a clever and false hypothesis. A theory far from reality of a nature whose living beings are perpetuated by obeying the law of repeating the characters that identify the group.

In the first volumes of the British periodical *The Oracle of Reason* (1842 and 1843), William Chilton, co-founder and editor, published the article “Theory of regular gradation.” A world without God was possible thanks to Lamarck. And the best way to learn more about his theory was to read *Principles of Geology*. In 1844, *Vestiges of the Natural History of Creation* by Robert Chambers was published. He ignored Lamarck’s name for years, only including a laughable note from the sixth edition (1847) on. Why? In the preface to the tenth edition (1853), Chambers recognizes that he knows the Lamarckian hypothesis, which he considered inappropriate to explain the existence of living species. To understand Chambers’ disregard, it is necessary to read the thorough and extensive review published in 1845 by the *North British Review* on the occasion of the fourth edition of the *Vestiges*. An anonymous columnist raises the injustice of forgetting to include the *system of progressive development* of the skilled and esteemed Professor Lamarck that, conceptually identical to the *Vestiges*, was superior because it establishes intelligible causes to justify the hypothesis of successive changes that transform species.

In the mid-1840s, owing to the French botanist Frédéric Gérard, a follower of Lamarck, the master’s approach took identity as the *théorie de l’évolution des formes organiques* (1845). Gérard used the Lamarckian model to explain Earth’s history. The fossil record indicated what had happened in nature from the origins to the present. The *theory of evolution* was a possible biological law that was simple, direct, and comprehensible. In contrast, the geologists Alonzo Gray and C. B. Adams were not in favor of the widely known theory of transmutation (Gray and Adams 1854). They believed in the miracles. As evident in their book, *Elements of Geology* (1852), they have no doubt about the direct intervention of the Creator. However, it is from a position that does not prevent them from discussing the transformist option, which allows them to recall Lamarck’s theory as an explanation of a correlative natural order from the simple to the complex through the progressive increase of anatomical structures.

Other evidence. At the academic meeting held on the 20th of April 1855 at the Royal Institution, Professor Thomas Huxley took to the floor to discuss some of the zoological arguments on the hypothesis of the progressive development of animal life. He wondered what was the significance of extinct species. The answer was essential. Living beings differed in every era, and the chronological substitution of species was something accepted by all. An undeniable fact. For Huxley, the issue under debate was not what happened but to explain how changes happened. The law regulating the phenomenon remained to be determined. He had to wait 4 years to know that natural selection was the answer. Huxley explains it in his article “The Darwinian Hypothesis” for *The Times* (26 December 1859). In his exposition, the figure of “the famous naturalist” Lamarck appears, one of those privileged rare minds able to reject miracles. Minds willing to refuse the creationist dogma. Lamarck correctly interpreted the process but was wrong to establish evolutionary law as organic modification induced by the environment and inherited by offspring.

The end. In 1859, oblivious to the *Origin*, the French botanist Dominique Alexandre Godron recognized the merit of Lamarck as a leader of the transmutationist movement. In his treatise *De l’espèce et des races*, he advocates that his compatriot deserved to be considered head of the naturalist school, in defense of the theory of the mutability of species through the action of external agents and reproduction. The Swiss naturalist Louis Agassiz, a self-confessed anti-Darwinist, also recalled Lamarck’s role. In his book *An Essay on Classification* (1859), Lamarck, along with his *Philosophie Zoologique*, is emphasized as a defender of species variability. An approach in which the structural complexity of animals is defined by a succession of organizational degrees arranged according to continuous series.

Conclusion

The reputed French biologist Jean Rostand writes in *Esquisse d’une histoire de la biologie* (1945) that *Philosophie Zoologique* was a failure that

soon fell into indifference. Rostand was wrong. It was not so. The Lamarckian hypothesis did not leave his contemporaries indifferent. The theory was known, discussed, and integrated into the naturalist discourse as an alternative to the conservative creationist model. In Great Britain, Lamarck's ideas provoked a major debate. A relevant occurrence as some of the scientists involved – Lyell, Huxley, etc. – were part of the scientific group in which Darwin conceived of natural selection. Huxley's testimony, in particular, presents Lamarck as responsible for the debate on the chronological substitution of species. For its part, *Principles of Geology* was a fundamental element for the dissemination of the Lamarckian ideology, for both its detailed analysis and its widespread circulation. Huxley was right to assert that in England, thanks to Lyell, they did not forget Lamarck. For decades, *Philosophie Zoologique* was the evolutionist reference. Until the publication of the *Origin of Species*, no other treatise existed on the subject. It is the first one. It created the school. It established a new concept of nature by applying another method of investigation. It laid the foundations of the transformist, transmutationist, and evolutionary model – the adjective does not matter. It was, as the Darwinist Ernst Haeckel writes in his *History of Creation*, the first rational exposition on the *genealogical doctrine* that reached the final consequences (Haeckel 1876). And it was by the Chevalier de Lamarck. In short, *Philosophie Zoologique* changed the perspective of nature, leading to the beginning of modern biology. It was not a coincidence. The author explains it in the preamble. His goal was to write a monograph on living bodies entitled *Biology*. In the end, he presented his research on the characters, organization, development, diversity, and abilities of the animal kingdom using the classic format of philosophy. A dull title for a clear, innovative, and revolutionary idea: the origin of living beings through evolution.

Jerome H. Barkow

Rick O'Gorman
Department of Psychology, University of Essex,
Colchester, UK

Definition

Jerome (Jerry) Barkow is a biosocial anthropologist whose work has emphasized how our evolved psychology provides the infrastructure of culture and whose work has been a prescient call (Barkow 1973, 1994) for an evolutionary psychological anthropology. His often pioneering work embraces how our pan-primate tendency to form hierarchies helps to generate – and always underlies – human social structures (Barkow 1975a, b, 1980a, 2014b). He co-edited the foundational text and rallying cry for evolutionary psychology, *The Adapted Mind* (Barkow et al. 1992), drawing together his earlier recognition for evolutionary approaches to ground our study of human behavior. Barkow's work runs a broad gamut, including work that was a forerunner in the evolutionary study of gossip (Barkow 1992), happiness (Barkow 1997), and, more recently, the likely psychology of extraterrestrials (Barkow 2000,

2014a, forthcoming). He has also been vocal that explanations at different levels of organization (such as those at the individual versus sociological levels) must always be compatible with one another but can never be in competition (Barkow 1989a, 2006a).

Introduction

Jerry Barkow is an interdisciplinary, biosocial anthropologist who has spent his academic career at Dalhousie University, Canada. He has been a visiting professor at the Institute for Cognition and Culture at Queen's University Belfast (QUB) and, following his retirement and appointment as a Professor Emeritus at Dalhousie, served as an honorary professor at QUB for 7 years.

Private Life

Jerry Barkow was born on January 18, 1944, in Brooklyn, New York, to Philip Barkow and Rebecca Gendler Barkow, the younger of two sons. He spent the first 20 years of his life in Brooklyn and worked selling ice cream, as a photographic technician, a postal worker, and finally a Social Investigator for the New York City Department of Welfare. He has lived most of his adult life in Canada and identifies as Canadian. Jerry was the first in his family to earn a university degree. He is married to Irma Juuti and has one son, Philip, one daughter, Sarah, and two grandchildren.

Academic Education

Jerry received his B.A. from Brooklyn College. While majoring in psychology, a course taken just prior to graduation with the late Gerald Henderson in Culture and Personality led him to seek interdisciplinary graduate training. He was accepted by the University of Chicago's Committee on Human Development, where he worked with psychological anthropologist Robert A. LeVine and ethologically oriented psychologist Daniel

G. Freedman. During his first summer, he was hired by a project on ethnocentrism that LeVine was conducting with then-Northwestern University psychologist Donald Campbell. Campbell gave Jerry a stack of his publications and he read them all carefully and with delight; Campbell's thought has been a lifelong influence on Jerry's own work and prepared him for his introduction to the work of Darwin and to ethology that Freedman provided. LeVine was beginning a project (involving infants) among the Hausa of northern Nigeria, and Jerry went off to Ahmadu Bello University and then to a small town nearby where he built a compound and lived for 15 months conducting his first fieldwork. His thesis topic addressed prestige and relative standing, comparing the ethos of Muslim Hausa and the more rural Maguzawa, a non-Muslim Hausa people. He substantiated his findings using four distinct methods. One of the findings was that the Maguzawa had lower self-esteem than did the Muslim Hausa, reflecting the Maguzawa's lower political power. This lesson that personal self-esteem, membership, group standing, and political power are intricately interlinked and apparently are the human heritage of the general primate tendency to form, maintain, and see the world through hierarchies ("hierarchizing") informed much of Jerry's subsequent evolutionary thinking about the relationship between our evolved psychology and our social structures.

Contributions to Evolutionary Psychology

Fieldwork Contributions

In keeping with his social-cultural anthropological training, Jerry's work has a substantial degree that is field-based. Several of his publications provide empirical data on the relationship between culture and our evolved psychology. For example, Barkow (1982) found that when the age grading social hierarchical system of the Migili (Koro) of Nigeria's Middle Belt collapsed, reciprocal and kin-directed altruism replaced them. An age grading system is a social organization based on a series of ranks, and one is

promoted as one gets older and shows appropriate qualities. For the Migili, the age grade of younger men was responsible for doing most of the heavy labor, including making the hills for the all-important yam crop. This is arduous labor and that age grade performed it for everyone, including women and older people. When the social organization collapsed, individuals were on their own. Data on who made hills for whom and whether or not there was reciprocity combined with coefficients of relatedness showed that the higher the relatedness the less likely that aid would be reciprocated; in contrast, among non-relatives, it was always reciprocated. Thus, a fundamental aspect of evolved psychology, reciprocal and kin-directed altruism, came to the fore when the social structure that had over-ridden it (for this task, at least) ceased to operate.

Working with a medical team in Indonesia, during the late Nineties, Jerry came across an evolutionary paradox (Barkow et al. 2001), which he framed as "why the Bugis know more about cooking than about nutrition." Why, apparently, did Bugis women have a stronger interest in their cooking ability rather than nutritional knowledge? Jerry wondered would not evolutionary theory predict a maternal ability to monitor her offspring's nutritional status and thus strive to provide the healthiest diet possible, given the local environment? As Barkow details, a physician member of the team explained why indigenous knowledge of infant and child nutrition was poor: how would a mother know whether the child's ill health was caused by a parasite, a disease, or diet? Barkow notes that evolution needs something to work with, and in this case there is no way that even the most observant and caring mothers can provide natural selection with genetic variance to select on. Skill in cooking, however, is an important cultural realm of competition, locally, and not just among the women themselves, so we get the historical development of an excellent cuisine (cookies, in particular). Ever the anthropologist, Jerry notes that a lesson for evolutionary psychology is that both evolution and their field have their limits.

Working in the city of Maradi in Niger during the first half of the Seventies, Jerry studied a

small panel of men intensively (Barkow 1975b). A status conflict existed between the ruling, French-speaking bureaucratic elite, and ordinary people. Jerry observed that the response of the latter was to seek to invalidate the prestige claims of the elite by arguing that only Islamic learning and practice merit respect – something the elite did not have, and so many people spent countless hours in religious study; those who had not had sufficient early Islamic education to have this option open to them suffered low self-esteem. Decades later, it is apparent that Jerry may have described one of the processes that has led to the spread of a fervent Islam in the region. The evolved psychological trait of hierarchizing is at the base of a vertically integrated explanation for a major socio-political phenomenon.

Links with Social-Cultural Anthropology

Jerry has repeatedly sought to engage his discipline with evolutionary thinking. At times he has done this with data, at other times by explaining how their view of human behavior is fundamentally flawed (Barkow 1978a, b, 1980b, 1984, 1989a, b, 1994, 2001; Barkow et al. 1978, 2013). “Sometimes the Bus Does Wait” (Barkow 2006b), the amusingly titled introduction to his edited book (Barkow 2006c), *Missing the Revolution: Darwinism for Social Scientists*, is at once a powerful deconstruction of the myths many social scientists hold of evolutionary psychology and a heartfelt plea for them to join the major human science intellectual revolution of our time. The tragedy here is that without evolutionary psychology’s theories of human nature the social sciences are condemned to explaining endlessly recurring fires whose ultimate causes they can never understand, a point made in the title of Jerry’s article (Barkow 2003), “Biology is destiny only if we ignore it.”

An important theme in Jerry’s work is that if cultural features were simply replicated, culture would be nonadaptive because environments change; old practices may no longer work or no longer be sustainable, while new opportunities appear: culture must not only be transmitted but added to and *edited* (Barkow 1975b, 1989a, 2014a; Barkow et al. 2012, 2013). Much of our

evolved psychology, he has long argued, was selected for in order to edit culture. Whom we attend to determines from whom we learn. Status shapes this strongly, biasing us to learn from those high in status as we attend to them (Barkow 1976a, b, 2014; Barkow et al. 2012).

Jerry has also incorporated other concepts into his work that are more commonly found in the animal behavior literature. Jerry has presciently looked at the notion of local adaptation, where the environment of adaptation is the culture (Barkow 1980a). In a quantitative study of conformity to the local ethos and reproductive success among Hausa townsmen (Barkow 1977), he provides evidence for selective pressure from culture in that men who conformed better to the ethos of their community (by not mentioning emotion-laden topics in a standardized setting) had more children than did those who did not conform as well. Population mobility and sociocultural change preclude the process from having any real genetic impact, in this example, but the results are compatible with the possibility that genetic impact from cultural traits may have played a role in our evolutionary history.

Links with Extraterrestrial Intelligences

Jerry is on the Board of Directors of Messaging Extraterrestrial Intelligence International (METI) and has ties to the SETI (Searching for Extraterrestrial Intelligence) Institute as well. In his articles (cited earlier), he reviews the processes believed to have led to our own species’ evolved psychology and then asks what if, on an exoplanet, those processes varied. For example, suppose an ETI (extraterrestrial intelligence) evolved in competition not with bands of conspecifics but with members of other species, would they therefore be selected to be obligate xenophobes? Suppose an ETI species did not have sexes and moved genes laterally but nevertheless evolved a high technology through a history entirely different from our own: what would their psychology be like? Competition is a human universal and is deeply implicated in our science, technology, and art and was likely produced at least in part by sexual selection: would the evolved psychology of a sexless species that could not have been

subject to sexual selection lack competitiveness? These are the fascinating questions Jerry has been asking in his most recent work, perhaps the ultimate exercise for an evolutionarily minded scholar! As we move to being a space-faring species the need for advice from evolutionary psychologists about what we may meet out there will only grow.

Definition

A twentieth-century scientist who integrated principles from ethology, ecology, and evolutionary biology with developmental psychology, Bowlby is most renowned for his scientific contributions of *attachment theory* in humans.

Introduction

John Bowlby’s early interest in child psychiatry and the influences of Sigmund Freud and Konrad Lorenz steered his career to become one of the most influential scientists in biology and psychology. His most famous works, such as *monotropy*, *attachment theory*, and the popular *environment of evolutionary adaptedness* (EEA), are still studied by numerous biological and psychological scholars. Evolutionary psychologists accredit Bowlby for being one of the first scientists to integrate biological and psychological principles in the study of human attachment.

Early Academic Training

Bowlby graduated from the University of Cambridge in 1928 after primarily studying developmental psychology (Rubinstein 2015); nevertheless, the young John Bowlby beheld a passion in working with children and medicine, which precipitated his pursuit to study child psychiatry. After receiving rigorous training as a child psychoanalyst at the British Psychoanalytic Institute, Bowlby began to behold an unorthodox perspective of the development of early human attachment (Bretherton 1992).

Professional Career and Scientific Philosophy

Konrad Lorenz’s research on *imprinting*, the behavior popularly associated with ducklings identifying any apparent caregiver as their parent, made Bowlby revise his conception of the child-parent relationship development (Cicchetti and

Greenberg 1991). Bowlby believed that ethological theories and principles like Lorenz's imprinting theory might apply to his understandings of psychology (Rubinstein 2015). As a psychologist who viewed Freudian psychology as being pertinent to behavioral science (Bretherton 1992), Bowlby encountered difficulty answering questions about the origins of human attachment or the development of children's affectionate relationships with their caregivers.

When Bowlby began considering that innate qualities may have contributed to human attachment, he concluded that the bond between the infant and caregiver is as crucial to the infant's survival as any other helpless and premature offspring (McLeod 2007). Bowlby observed that children's behaviors and habits that reflect their attitudes of intimate relationships were not learned, but he hypothesized that these behavioral qualities are innate to the human species (Bretherton 1992). To better understand what it meant to be *human*, Bowlby went on to become one of the first scientists to apply evolutionary theory to human psychological research (Rubinstein 2015).

Contributions to Evolutionary Psychology

Bowlby understood that unconditional love between the infant and caregiver is necessary for the infant's development until he or she can physically take care of his- or herself (Rubinstein 2015). Infants need relentless attention from others, and it is typically one caregiver that can establish a deep relationship with one infant at a time, which is a concept derived by Bowlby called *monotropy* (McLeod 2007). Contemporary research focusing on this attachment to an infant supports that the infant-caregiver attachment is unique to other familial attachments (Bretherton 1992; McLeod 2007). Monotropy is reported to be so significant to both the infant's personality development and relationship attitudes that failure to establish the bond entails negative consequences for the infant (McLeod 2007).

The maternal deprivation hypothesis conceived by Bowlby predicts that if the infant-

caregiver attachment is not established, deleterious habits and behaviors are likely to develop (Rubinstein 2015). However, the maternal deprivation hypothesis and collaboration with developmental psychologist, Mary Ainsworth, led to Bowlby's most famous contribution to the psychological community, *attachment theory* (McLeod 2007).

Bowlby's and Ainsworth's attachment theory posits that the absence of an infant's attachment to the caregiver ultimately affects the nature of subsequent relationships with others when the infant is mature (Bowlby 1982). Delinquency, reduced cognitive function, increased aggression, heightened risk for depression, and psychopathic traits have been observed in older individuals with little to none attachment to a caregiver during infancy (McLeod 2007). Observations in the pattern of occurrences when the infant smiles or cries while in the presence and absence of the caregiver are used to indicate attachment formation. As the emotional expressions grow with the infant, psychologists scrutinize them in order to learn more about mental disorders and how to treat them (Cicchetti and Greenberg 1991).

The significance of a successful infant-caregiver attachment to human survival led Bowlby to believe that the environmental pressures and problems endured by our ancestors were more extreme than the ones modern humans endure today. Bowlby was the first to coin a term that is ubiquitous to the science and research of evolutionary psychology, *the environment of evolutionary adaptedness* (EEA). Bowlby believed that a species' properties, biological and psychological, originated and evolved during its ancestral history. The EEA is not a single or specific time, place, or environmental condition; it is the broad range of times and environments that the species' properties adapted to (Bowlby 1982).

Evolutionary psychology countlessly derives many of its hypotheses and theories from Bowlby's concept of the EEA. Human psychological adaptations, such as memory, classical conditioning, fear, etc., are designed to solve problems encountered throughout human evolutionary history. On the other hand, modern environments, like Western societies, contain some drastically

different problems and selection pressures on humans. These novel environments and environmental features were not what molded human psychological and biological adaptations. Evolutionary psychologists acknowledge that discerning a species' EEA may help identify and understand the behavioral phenomena observed within that species.

Conclusion

John Bowlby's original interests in developmental psychology and medicine fostered his career interests to apply a different perspective to traditional psychology. As a trained psychoanalyst who was influenced by ethology, Bowlby was pressured to ask questions that concurrent psychologists condoned. Theories he has contributed to, like attachment theory, continue to be viewed as exemplars of the consilience between psychology and biology. Bowlby's position that innate psychological qualities facilitate and nurture human psychological phenomena, like the infant-caregiver attachment, made him one of the first scientists to think like an evolutionary psychologist.

Definition

Edward John Mostyn Bowlby (1907–1990), British child psychiatrist and psychoanalyst, author of the evolutionary theory of attachment.

Introduction

Since its origin attachment theory has become the most important paradigm in contemporary developmental psychology and its author, John Bowlby, is considered to be one of the greatest psychiatrist of the twentieth century and father of contemporary psychotherapy. Attachment theory is one of the most important psychological theories that can be applied to explain personality growth, behavior, and human relationships across the life course. Bowlby's theory of loss, grief, and mourning is acknowledged as one of the major theories of bereavement (Shaver and Fraley 2008).

The Origin of Attachment Theory

Bowlby's theory has its roots in ethological and evolutionary sciences, cybernetics, information processing, control and systems theory,

developmental psychology, object theory, and psychoanalysis (Bowlby 1958; Bretherton 1992). His interest in ethology is particularly noteworthy as it constitutes the basic structure of the theory (Ainsworth 1990) and its main tenet according to which relationship between mother and infant is a result of biologically rooted need for proximity that has its origin in the process of natural selection (Bowlby 1958, 1969/1982). In this way, Bowlby rejected the current psychoanalytic notion that relationship between mother and infant derives from oral gratification (Bretherton 1992) and simply occurs because the pleasure of being fed becomes associated with mother's presence (Cassidy 2008). He was dissatisfied with social learning theory as well, where dependency was seen as based on secondary reinforcement. He also negated precedence of fantasy over real life experiences. All that placed him on the margin of psychoanalytic circles, that he wished to belong to, despite notable differences in thinking. Although Bowlby's ideas were different from psychoanalytical ones, he remained interested in psychoanalysis and merely intended to reformulate clinical thinking with ethological concepts by taking into account the impact of real life experiences on children's psychopathology and by gathering empirical findings to support theory. When it comes to the method of building his theory, Bowlby was closer to Darwin than Freud, as he especially valued "hard data" obtained by observation (van der Horst 2011).

Two papers, *Forty-Four Juvenile Thieves: Their Characters and Home Life* (1944) and *Child Care and the Growth of Love* (Bowlby 1965), are the first publications where Bowlby's major conclusion about what are the conditions of infant's mental health was outlined (Bretherton 1992). He proposed that separation from primary caregiver and maternal deprivation are main factors in explaining children's psychopathology. He wrote, "the infant and young child should experience a warm, intimate, and continuous relationship with his mother (or permanent mother substitute) in which both find satisfaction and enjoyment" (Bowlby 1951, p. 13) in order to grow up mentally healthy and to develop effective personality functioning. Paper from 1951, which

was the WHO report on consequences of maternal deprivation on child development, is marked as the beginning of so-called *ethological era* in Bowlby's scientific development (van der Horst 2011).

According to Bretherton (1992), the following three papers are regarded as the first formal statement of attachment theory: *The Nature of the Child's Tie to His Mother* (1958), *Separation Anxiety* (1959), and *Grief and Mourning in Infancy and Early Childhood* (1960), and never published two papers on defensive processes in mourning (1962).

In 1969, Bowlby started working on the first volume of the attachment trilogy: Attachment and Loss. volume 1. Attachment (1969/1982); volume 2. Separation (1973/1985); volume 3. Loss. Sadness and Depression (1980/1991).

Basic Tenets of Attachment Theory

Attachment can be described from two perspectives: as a behavioral control system with its specific predictable outcome or as an emotional bond, a relationship between two individuals.

From evolutionary perspective, attachment is one of the innate motivational systems that provides survival advantage (Bowlby 1969/1982; Cassidy 2008). It has behavioral, affective, cognitive, and neurophysiological components. The main goal is to obtain and keep the proximity or accessibility to a discriminated primary caregiver, which gives the child protection (survival function) and a feeling of security (psychological function). The biological nature of the system is responsible for instinctual activation of attachment behaviors on the part of the child. These behaviors operate in a goal-corrected manner, which means they are flexibly used according to the needs of the child and current situation (Bowlby 1969/1982). When attachment system is activated – by cues of external danger or any kind of distress – it causes neurophysiological arousal and inhibits working of other behavioral systems (such as exploration). In this state a child seeks proximity and comfort from attachment figure, whose role is to respond to the signs

of distress in an effective manner. Individual differences in organization of the attachment system are shaped by interaction with a specific caregiver (attachment patterns, attachment styles, attachment strategies). Moreover, attachment experiences are represented in internal working model – cognitive–affective representations of *self*, attachment figure, and interaction between them. These structures shape expectations, memory, perception, and behaviors. They are also used to appraise the situation, plan one's own action, and its consequences. They act predominantly in an automatic manner. What plays vital role in organizing memories of attachment experiences is an affect (Pietromonaco and Feldman-Barrett 2000). In addition, affect activates content of working models of attachment.

Attachment described as an affectional bond refers to an intimate emotional bond a weaker and less experienced individual has with another one, regarded as stronger and/or wiser (Bowlby 1969/1982, 1973/1985, 1980/1991, 1988). It is formed first between a child and a care provider, and between adults in later life. According to Ainsworth (1989) it is not a dyadic tie but a characteristic of an individual. Therefore, one can be attached to someone who is not in turn attached to him or her. Attachment bond was described by Bowlby and Ainsworth as a specific type of affectional bond. It is persistent, involves a specific person with whom one has emotionally significant relationship, and desires to maintain proximity and contact with (Cassidy 2008), as it is in the case of any other affectional bond. But additionally, attachment bond serves a specific function: security and comfort are looked for in this relationship. As Bowlby outlined, breaking of this bond (caused, for example, by separation or loss) has profound impact on well-being of an individual, which does not take place to the same extent when other, nonattachment bonds are lost (Bowlby 1969/1982).

Bowlby emphasized the importance of emotions that arise in attachment relationships (Bowlby 1969/1982, 1988) – joy and sense of security when proximity with caregiver is maintained; jealousy, anxiety, and anger when the bond is threatened; and sadness, grief, and depression when the bond is broken. He stated

that these affective responses are a product of evolution. According to Bowlby, positive affects accompanying attachment relationship and negative affects accompanying loss or threat of loss motivate child to maintain this bond. They serve to alert the caregiver to the child's interest in maintaining the relationship (Bowlby 1973).

Attachment theory is described by some researchers as the joint work of John Bowlby and Mary Ainsworth (Bretherton 1992; Cassidy 2008). Ainsworth introduced the notion of individual differences in patterns of attachment, administration of Strange Situation, the concept of the attachment figure as a secure base of exploration, and the concept of maternal sensitivity.

Conclusion

Attachment theory has a lot to offer in the field of infants' mental health. Within the attachment framework, where mental representations of attachment (working models) are considered to give an access to organization of attachment system in adolescence and adulthood, there is also a possibility of studying attachment and its contribution to personality development and psychopathology in adulthood as well. There is growing body of research in the field of intergenerational transmission of attachment and its stability throughout life cycle. It is not surprising then that the attachment theory is used in the prevention and intervention programs for supporting early attachment security, in foster and adoptive care, in child care policies, in psychotherapy – just to enumerate few ways of applying it in practice.

who founded attachment theory, drawing on evolutionary theory and ethology, cybernetics, and cognitive theory.

Introduction

John Bowlby, a psychoanalyst and child psychiatrist, sought to reform and modernize psychoanalysis to give it a scientific basis, as he was unsatisfied with parts of its metatheory. Bowlby was particularly concerned with the psychoanalytic explanation of why children develop strong emotional bonds – attachments – to their caregivers, monitoring proximity to the caregiver(s) and showing distress upon separations. Attachment was at the time considered secondary to other processes, such as special forms of psychical energies, which Bowlby argued was unscientific. As outlined below, Bowlby came to draw on ethology, cybernetics, and cognitive psychology and argued that humans and other primates over the course of evolution have developed an attachment behavioral control system with a goal of maintaining proximity to caregivers. This attachment behavioral control system was proposed to have served an evolutionary function of protection from predators and natural dangers, thus increasing survival and reproduction. Bowlby, who himself had experienced an influential separation from a caregiver (i.e., his nanny), also emphasized the importance of actual experiences with caregivers (i.e., quality of caregiving) for children's psychological development and the need for testable psychological theories and empirical methodology using prospective designs.

Definition

Edward John Mostyn Bowlby (1907–1990): A British child psychiatrist and psychoanalyst

Childhood and Education: Development of an Interest in Close Relationships with Caregivers and Effects of Early Separations

In keeping with the proposals of attachment theory – that early experiences with caregivers affect the development of the person and how we come to view ourselves and others – roots to Bowlby's lifelong interest in the importance of close and

enduring relationships between children and their caregivers may partly stem from his own early experiences. Bowlby was born as the fourth of six children in an upper middle class family in London, his father a doctor and surgeon to the royal family. The family situation was typical for its social class of the time, with nanny's taking care of the household and the children. Bowlby's interactions with his mother were therefore limited and, apart from holidays, typically restricted to her reading aloud to the children during an hour in the afternoon. It is thus not surprisingly that Bowlby formed his first strong emotional bond to one of his nannies, Minnie. However, Minnie left the family when Bowlby was only 4 years old. Bowlby admitted that this was a painful loss to him, and he likened it to losing a mother figure (Van Dijken 1998). During the First World War, when he was 10 years old, Bowlby was sent to boarding school together with his brother so that they would escape the presumed bombings of London. Bowlby however thought this was just an excuse, and that he would have been sent to the boarding school anyway, as this was the traditional first step towards becoming a gentleman (Holmes 1993). Thus, these early experiences may have affected his interest in the potential negative effects of early separations from caregivers and the importance of children's experiences with their caregivers.

After boarding school Bowlby went to the navy cadet school to embark on a career as an officer. However, Bowlby soon got tired of this life, partly as he thought it would not give him opportunities to change the world for the better (Van Dijken 1998). Bowlby then studied medicine at Cambridge University, following in the footsteps of his father. He then came in contact with developmental psychology, gave up medicine, and chose to work as a teacher for a year. This experience, which included 6 months at a school for maladjusted children, came to have a marked influence on him, as he observed that many of the maladjusted and antisocial children he was working with had experienced a difficult childhood, including separations from their caregivers and being cared for by multiple substitute caregivers. Through a colleague Bowlby also got in contact

with psychoanalysis. Indeed, Bowlby regarded this as the most important 6 months of his career, realizing that psychological problems should be understood at a developmental level and being influenced by experiences with caregivers. After his year as a teacher Bowlby studied psychology at Trinity College and worked with maladjusted children before eventually enrolling at University College Hospital in London to qualify in medicine and pursue a career as a child psychiatrist.

Bowlby and Psychoanalysis: A Complicated and Conflicted Relationship

To become a child psychiatrist he also enrolled himself at the institute for psychoanalysis, as psychoanalysis was a good basis for working with children. However, he first had to train in adult psychiatry, which included going through psychoanalysis himself, which he did with a coworker of Melanie Klein (his supervisor), Joan Riviere, as his analyst. Bowlby agreed with Melanie Klein and her colleagues that children's first year are important for their subsequent development but disagreed heavily with the psychoanalytical explanations of the processes responsible for children's development and functioning. When discussing attachment theory in relation to psychoanalysis, Bowlby (1980) referenced Rapaport and Gill (1959), who described the psychoanalytical metatheory in terms of postulates regarding five principles (see ► [“Psychodynamic Foundations”](#)). Bowlby specifically questioned the “dynamic” and “economic” principles of the metatheory, which he termed the “psychical energy model.” According to this model humans are endowed with distinct types of psychical energies that builds up and needs discharge in order for homeostasis and that children's development is affected by the channeling of these energies and infantile fantasies about their caregivers. Bowlby felt that this postulation was unscientific and that it did not sufficiently acknowledge the importance of children's actual experiences with their caregivers. Indeed, according to these theories attachment was secondary to processes such as feeding

and psychical energies. Bowlby thus termed these theories “secondary drive theories.” After being blocked several times Bowlby eventually got accepted into the British Psychoanalytical Association, stubbornly outlining his own ideas in his thesis “The influence of early environment for the development of neurosis and neurotic character” (1940). Interestingly, Bowlby called Klein his anti-thesis and felt that he learned more from the social workers he was working with at a child psychiatrist clinic than he did from his psychiatrist colleagues.

Bowlby was part of a “third-wave” psychoanalytic school, often referred to as the British school of objects relations, and which also included for example Donald Winnicott, Michael Balint, Harry Guntrip, and Ronald Fairbairn. Bowlby was particularly influenced by Donald Winnicott, who shared his view that children come into the world sensitive to social interactions and in need of healthy interactions to develop well. Although the object relation theorists agreed on some things there were also notable differences. A major difference, according to Bowlby, was that the other object relation theories, in comparison to his attachment theory, lacked an alternative to the instincts/drives proposed by Freud. Indeed, Bowlby felt strongly that in order for change to occur there had to be alternatives to Freud’s theory. Of course, the alternative that Bowlby came to suggest was attachment theory. Bowlby was however careful to state that attachment theory is a much more narrow theory than psychoanalysis, pertaining to one behavioral system, and not a theory that could exchange psychoanalysis as a whole.

Given that Bowlby contested some of the core tenets of psychoanalytic theory, that psychoanalysis at the time was rather territorial, and that the scientific methodology Bowlby argued for was largely alien to the psychoanalytical field, it is maybe understandable that Bowlby’s ideas were largely rejected by the psychoanalytic community and that Bowlby was deemed a reductionist that was willing to sacrifice central psychoanalytic concepts for what was observable. Bowlby was vice president in the British Psychoanalytical Association 1956–1961, under Donald Winnicott,

but got increasingly ostracized, and after his position as vice president ended he gradually decreased his involvement and settled for passive membership. Bowlby was saddened, and puzzled, that his work in trying to modernize the psychoanalytic theory was rejected, particularly as he thought that attachment theory was in many ways in accordance with some of Freud’s ideas, although formulated in modern scientific terms. For example, Bowlby agreed with Freud that we have psychological defenses against anxiety, although he formulated the defenses based on information processing and memory in terms of cognitive-affective strategies for dealing with threatening information (i.e., defensive exclusion and shifting of attention).

Attachment theory, together with the empirical research it has generated, has however become an important part of several modern psychoanalytical approaches and is now often seen as an important empirical foundation of psychoanalysis (Fonagy et al. 2008). An important factor in this rapprochement was the advent of the Adult Attachment Interview and other representational and linguistically based methods used for examining attachment in older children, adolescents, and adult (Main et al. 1985), which were developed based on Bowlby’s concept of internal working models of self and others (see ► [“Offspring–Parent Attachment”](#)).

Scientific Work and Collaborations: Scientific Evidence for the Importance of Close Relationships with Caregivers, Negative Effects of Early Separations, and the Development of Attachment

After the Second World War, Bowlby became head of the Tavistock clinic’s child department, where he remained until his retirement in 1972. Tellingly, he immediately renamed the department “the department for children and parents,” to acknowledge a family perspective on children’s psychological problems. In 1944 Bowlby published a collection of clinical case reports, in which he compared the background of 44 children treated for antisocial behaviors with an equal

number of children treated for other behavior problems. Bowlby found that the antisocial children had experienced markedly more losses and separations from their primary caregivers. Negative effects of separations from caregivers were also reported in children who were evacuated from their families in London (i.e., separated) so as not to have to suffer the bombings (Freud and Burlingham 1943). Reinforced by these findings, Bowlby went on to seek more evidence for the untoward effects of separation and the development of attachment.

Bowlby started up various scientific collaborations, most notably with James and Joyce Robertson and Mary Ainsworth. The Robertson couple, inspired by an ethological approach, conducted extensive, videotaped observations of children's reactions prior to, during, and after being separated from their caregivers in the context of hospital or orphanage care. These now classic observations demonstrated with brutal clarity how the children suffered (e.g., Robertson and Bowlby 1952). Bowlby and the Robertson couple attributed the ill effects to the (temporary) loss of the caregiver(s): "from empirical observation we suggested that the young child's hunger for his mother's love and presence is as great as his hunger for food" (Bowlby, p. xiii). The validity of the observations was initially questioned, and the reactions attributed to factors other than the separation from the caregiver(s) per se, such as the strange environment. However, the observations eventually initiated a revolution in child health care in the beginning of the 1950s. In this regard Bowlby was particularly thankful to Winnicott, whose clinical work helped influence policy change.

Mary Ainsworth initially conducted naturalistic observations of children's attachment behaviors in Uganda where she followed a number of children and their parents during the children's first year (Ainsworth 1967). This provided Bowlby with invaluable information about the early development of attachment (see ► ["Offspring-Parent Attachment"](#)) and how individual variations in caregiver behavior are related to systematic variations in children's organization

of attachment (see ► ["Individual Variations in Attachment"](#)). As regards the development of attachment, Ainsworth found that most children seemed to develop an attachment during the second half of the first year, whereby they started to direct their attention and behaviors selectively towards their caregivers and monitor their whereabouts, used the caregivers as a reference point for exploration of their environment (i.e., as a secure base), retreating specifically to the caregivers in times of distress (i.e., as a safe haven), and seeking to remain in proximity with their caregivers and protesting separations from them.

The WHO Report and the Seminar Group: Developing a Theory of Attachment Based on Evolutionary Theory and Ethology, Cybernetics, and Cognitive Psychology

In 1950, Bowlby was asked by the World Health Organization to make a report on the available knowledge concerning factors that may affect children's psychological health, particularly as regards the effects of separations. The report "Maternal Care and Mental health" was published in 1951, and through his work with the report Bowlby learned that other researchers and clinicians shared his ideas about the effects of early separations from caregivers. However, as discussed by Bowlby the WHO report had one major limitation, "whereas it had much to say about the many kinds of ill effects that that evidence shows can be attributed to maternal deprivation. . . it said very little indeed about the processes whereby these ill effects are brought into being. . . how does it come about that one or another of the events included under the general heading of maternal deprivation produces this or that form of psychiatric disturbance" (Bowlby 1980, p. xii)? Bowlby thus started turning his attention more towards understanding the nature of the special relationship – "tie" – between children and their caregivers.

After the WHO report Bowlby received funding that he used to start a seminar group, to

which he invited participants from various academic disciplines including biology, psychiatry, psychology, and social anthropology. If attachment is not a secondary drive but a primary motivation in its own right, what is it then, and how to explain it in scientific terms? The contact with ethology, through the pioneering control system ethologist Robert Hinde, got Bowlby in contact with the ethological work by, for example, Konrad Lorenz (1963) and Niko Tinbergen (1951). Their work included the phenomenon of imprinting seen in some species, such as birds, which shows some similarities with behaviors in mammals (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). Bowlby realized the potential of explaining human children’s propensities for developing strong and enduring bonds to their caregivers using ethological principles. Birds, although able to find food for themselves nonetheless developed bonds to their parents and followed them wherever they went. Thus, the bond must have served some other evolutionary function than feeding.

Bowlby also got in contact with Harlow’s (e.g., 1958) research with infant rhesus monkeys and surrogate mothers, extending the findings on imprinting in a species more closely related to humans. This became particularly important for Bowlby’s subsequent formulation of the attachment system as a primary motivational system (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). Bowlby visited Harlow, and although he explicitly questioned the methods Harlow used in his experiments with rhesus monkeys on ethical grounds, Harlow’s experiments gave Bowlby invaluable information. Indeed, they clearly indicated that the need for a close and enduring relationship with a caregiver – or attachment figure – is a primary motivation (cf. instinct) and not a secondary result of feeding. Bowlby, drawing from Darwin’s evolutionary theory as well as ethological concepts and research, argued that this “instinct” is a behavioral control system that has evolved and been retained because it has served a particular function in our evolutionary history. This function, according to Bowlby, is

protection from natural dangers such as predators, which follows from the predictable outcome of activation of the attachment system, proximity to caregivers. The similarities between humans and many other species regarding attachment bonds could, according to Bowlby, be explained with the notion of convergent evolution, as protection from predators have been common to many species of animals.

Bowlby also drew from cognitive theory and cybernetics in his formulation of the attachment system and its development. Bowlby was for example inspired by Piaget’s (1955) theory about children’s cognitive development, which came to influence Bowlby as regards the importance of cognitive development for the development of attachment during the early years. For example, older children are more able to endure separations due to their more advanced cognitive ability and perspective taking. Young’s (1964) and Craik’s (1943) theories, postulating that animals construct cognitive representations of the world, also influenced Bowlby in his proposal that the child’s experiences with his/hers attachment figures give rise to internal working models (IWMs; see ► [“Offspring–Parent Attachment”](#)) or affective-cognitive representations of self and others. Bowlby used the terms organismic and environmental models for these IWMs, which he argued were complementary. If a child is responded to in such a way that (s)he comes to perceive others as accessible and loving, (s)he will perceive him-/herself as lovable. Thus, when the IWMs are formed they are believed to affect how the child sees him-/herself, and how (s)he behaves in relation to close others, particularly in situations when the attachment system is activated. These models are hence important for predicting future situations with caregivers and important others and for efficient goal-directed behavior whereby the individual organizes his/her behavior based on the IWMs. This also provided Bowlby with an explanation of why children showed individual differences in attachment behavior and why children who had suffered from separations from their caregivers, and/or dysfunctional caregiving (i.e., had become insecurely attached),

many years later could come to show difficulties in developing close relationships, be described as affectionless and cold, or display antisocial behavior problems (see ► [“Individual Variations in Attachment”](#) and ► [“Individual Variations in Attachment”](#)).

Bowlby published the main tenets of attachment theory in three articles, “The nature of a child’s ties to his mother” (1958), “separation anxiety” (1960a), and “Grief and mourning in infancy and early childhood” (1960b). These articles, although initially largely ignored within psychoanalysis, were well received by researchers within developmental psychology, and Bowlby became a member of the medical research council in England. Bowlby thus got more time to think and write and subsequently published his classic book trilogy – attachment and loss – (1969, 1973, 1980), where he outlined the tenets of attachment theory in more detail, expanding on the three articles he had previously published.

Research Immediately Following in the Footsteps of Bowlby: Individual Differences in Attachment

Ainsworth (1967) had noted that the Ugandan children seemed to develop different strategies for maintaining proximity to their caregivers and that this seemed to depend on how the caregivers responded to the children’s signals. Seeking to replicate her Uganda findings in America, Ainsworth later devised a semi-structured laboratory observation, for which she methodologically drew on the ethologically inspired separation and reunion observations that the Robertson couple and Bowlby had used (e.g., Ainsworth et al. 1978). This laboratory observation, which induces slightly increasing levels of stress by means of a strange environment, a stranger, and two short separations from the caregiver, was deemed necessary to be able to observe children’s varying strategies for organizing their attachment behaviors in relation to their caregiver. Indeed, whereas the mere presence of Ainsworth in Uganda, where white women were uncommon,

had triggered the attachment system of Ugandan children, this was not the case in American children. The laboratory observation, which is called the strange situation procedure (SSP), is still today the most widely used method for observing children’s organization of attachment to their caregivers.

Briefly (see ► [“Individual Variations in Attachment”](#) for a thorough discussion), Ainsworth and her colleagues’ research indicated that children whose caregivers noticed the infants signals and responded timely and sensitively (particularly during distress, i.e., when the attachment system was activated) became securely attached to their caregivers, as indicated by a balance between the attachment system and an exploratory system. That is, secure children are able to use the caregiver(s) as a secure base from which to explore the environment when there are no signals of danger and to use their caregivers as a safe haven to return to for comfort and protection when distressed. Ainsworth and colleagues also identified two patterns of insecure attachment, insecure-avoidant and insecure-ambivalent/resistant, who do not show the same ability to use the caregiver as a safe haven and secure base, and which respective organization of behavior in relation to their caregiver could be predicted by specific patterns of caregiver insensitivity. Although Bowlby had argued from the start that the quality of caregiving is crucial to variations in attachment, he lacked an empirical method for examining caregiving in relation to attachment and hence focused on the effects of separation which were readily examined during the aftermath of the Second World War. He was therefore hugely grateful to Ainsworth for her contribution, and to acknowledge her Bowlby named his last book about attachment after one of her concepts, “A secure base” (Bowlby 1988).

Mary Main, a PhD student of Mary Ainsworth, later identified a fourth quality of attachment, disorganized/disoriented attachment, when seeking to understand the inexplicable and contradictory behaviors shown by some children who were therefore unclassifiable using Ainsworth’s established patterns (Main and Solomon 1990;

see ► [“Individual Variations in Attachment”](#) and ► [“Disorganized Attachment and Reactive Attachment Disorder”](#) for a more thorough discussion). These children, she found, had one thing in common: a (momentary) breakdown in the organization of attachment behaviors in relation to the caregiver. As opposed to secure and organized insecure children (i.e., avoidant and ambivalent), these children could not maintain an organized strategy in relation to their caregivers in the strange situation. Main argued that a cause of this breakdown in behavior is that the attachment figure (i.e., source of safety) is simultaneously represented as a cause of alarm. She termed this “fright without solution,” an unsolvable behavioral paradox of simultaneously seeking to approach and avoid or escape the caregiver. Bowlby’s (1980) notion of “segregated systems” provided important guiding principles for Main’s theory of the development of disorganized attachment, which was in turn received favorably by Bowlby (Duschinsky 2015). Main and colleagues argued that disorganized-disoriented attachment is most consistently predicted by frightening/frightened behaviors on behalf of the attachment figure (e.g., Main and Hesse 1990).

Conclusions

Bowlby sought to develop a scientifically based theory for the phenomenon of attachment between children and their caregivers, to reform the parts of the psychoanalytical metatheory that he could not accept. In so doing Bowlby drew on his own work as a child psychiatrist, his scientific collaborations and the information he gathered from the seminar group he started and which included participants from various scientific disciplines, most notably ethology and cognitive psychology. A notable feature of Bowlby’s work was thus an openness to draw on and integrate available knowledge from various scientific disciplines. Bowlby concluded that humans, as some other animals, are endowed with an attachment behavioral control system, which functions to seek and

maintain proximity to (usually) protective caregivers and which thereby increases the chances of survival and reproduction.

John Hartung (1995) Love Thy Neighbor

Reza Ziai

Psychology, Penn State University, Beaver, USA

Synonyms

In-group morality; Neuroethics; Religion

Definition

People are more likely to harm those perceived to be members of an out-group in a manner in which they would not harm members of one's in-group. When someone in one's in-group transgresses against a social contract, we are more likely to "look the other way" than if it were a member of the out-group performing the same behavior (Jost et al. 2008; Staub 1999; Tajfel 1982).

Introduction

In 1995, John Hartung's article, *Love Thy Neighbor: The Evolution of In-Group Morality*, appeared in *Skeptic* magazine. In it, the SUNY anesthesiologist and anthropologist explains how the Bible is a blueprint for in-group morality, out-group homogeneity, and world domination. The article uses passages from the Old Testament to highlight the interplay between religion, a proximal factor, and ultimate factors described by evolutionary psychology. Specifically, he shows how moral and ethical decrees against murder and theft outlined in the Bible apply to one's in-group but not to an out-group – for the sole purpose of competitive gain. Realistic conflict theory (Campbell 1967; Sherif et al. 1961), a concept heralded by many proponents of the Standard Social Science Model (Cosmides and Tooby 1992), is cast in Hartung's article as an analogue to the distal concepts of kin selection and to the co-opting of resources of one's rivals (Buss 1999). Hartung's article resurfaced in 2006 in Richard

Dawkins' *The God Delusion* and given the current state of polarization in social relations at the time of the drafting of this submission; there is hope that a new dialogue may emerge.

Intergroup Dynamics

From the standpoint of evolutionary psychology, it makes perfect sense to love, be friendly, and to be open with our tribe, family, or race. However, this dynamic is bidirectional. Humans also have a biological preparedness to protect one's in-group from outsiders and be suspicious of those who are "other" or "not like us" (Cikara and Van Bavel 2014; Kappeler and van Schaik 2006). Indeed, we not only have positive feelings about those who are perceived to be "one of us" in terms of norms, customs, and values, but we also have strong *negative* reactions toward those who are deemed to be somehow "other." For example, when African Americans and whites were shown pictures of one another, they both showed elevated levels of activity in the amygdala (the brain region associated with fear and aggression) (Wheeler and Fiske 2005). Perhaps even more chilling, 15–20% of Republicans and Democrats (US citizens) feel as though we would all be better off if large numbers of the opposing political party "just died" (Kalmoe and Mason 2019).

This in-group/out-group effect extends to features significantly less salient than race or political affiliation. Arbitrary and trivial features such as insignias on T-shirts (Cialdini et al. 1976) and art preferences (Tajfel et al. 1971) form what psychologists call minimal groups and known to trigger tribal tendencies and parochial biases. Whether from an evolutionary standpoint or from a social scientific one, preferences for one's group allow for benefits to flow to in-group members and justify hostilities toward out-group members. Interesting, and less discussed in the literature, a strong preference for one's in-group has been shown to be a better predictor for prejudice than overt hatred of an out-group. In other words, disgust for "the other" may not be as powerful of a motive for hostility as is a strong preference for one's in-group (Greenwald and Pettigrew 2014).

The Biology of Morality

In Hartung's article, he cites the work of Nancy Segal (1984) showing that identical twins are more likely to use the word "we," cooperate, and get the job done quicker than fraternal twins. This is hardly surprising given the work of W.D. Hamilton (1964) who showed that acts of altruism will be directed more toward identical twins (the degree of relatedness, or r , being equal to 1) than those who are more distantly related (full siblings, $r = 0.5$; half siblings, $r = 0.25$; first cousins, $r = 0.125$; etc.). According to Hartung, this is the scientific principal which Moses' edict to love thy neighbor as thyself rests upon. For if one was directed to love thy neighbor as thyself, it would be no problem doing only so as long as one's neighbor was construed to be "like us" in a very fundamental way. But if a group or individual was considered "other" or "less than," whether in some real or perceived way, mandates to avoid murdering them could be given a pass. In short, "thou shalt not kill" meant "thou shalt not kill another Jew," and "love thy neighbor" meant "love thy neighbor, as long as that person is also Jewish."

Who Is Thy Neighbor?

According to Hartung's quoting of the Old Testament, one's neighbor isn't merely a person who is being victimized or in need of help as some have interpreted it. In fact, Hartung goes to great length to show that murder in the OT is not only *not* wrong, but it is in certain instances, divinely commanded. When the Lord of the OT commanded Moses to tell others to not kill their countrymen, it should be noted that this was at a time where one's countrymen were essentially people living right next door. What this meant was that one's neighbor was both (a) nearby and, therefore, (b) similar to one's self. Hartung summarizes this succinctly: "...when the Israelites received the love law, they were isolated in a desert. According to the account, they lived in tents clustered by extended families, they had no non-Israelite neighbors, and dissention was rife."

As predicted by literature supporting in-group/out-group theory, the law to not kill one's neighbor was given a pass when the person being killed was no longer construed as a "neighbor."

John Hartung's analysis of the Old Testament has received strong criticism from Jews and Christians not only for his use of evolutionary theory to describe cultural practices, but for his tongue in cheek style in doing so. He quips that "although Moses may not have known about natural selection," it is as if he "had a sense of Hamilton's inclusive fitness." Although Jews are one of the most persecuted groups in modern times, Hartung pulls no punches when he suggests they did not hesitate in committing genocide themselves.

They should be utterly destroyed and should receive no mercy but be exterminated as the LORD commanded Moses. (Joshua 11:20)

Utterly destroy all that they have; do not spare them, but kill both man and woman, infant and suckling. (I Samuel 15:3)

Some may read this in Hartung's paper and jump to the conclusion that he is biased on this topic merely due to his association with Noam Chomsky. However, it should be noted that Napoleon Chagnon, Richard Dawkins, Robert Trivers, and many others were included in the list of people Hartung corresponded with for the drafting of his document (1995).

Religious Justification

"The point, however, is not that such phenomena were unique to the ancient Israelites. Far from it. Indeed, given the ubiquity of in-group/out-group double standards around the globe and throughout history, the propensity for in-group morality appears to be an attribute of human nature" (Hartung 1995). Hartung is correct, but his article only weighs in on the OT. Had he delved into the passages from other sacred works, this author is certain he would have had no difficulty in procuring additional verses to support his thesis. One reason most people do not hear of these verses as often is because they are cherry picked to "play nice" and keep things clean and friendly. Take for example this oft cited verse from the Quran:

...if any one killed a person, it would be as if he killed the whole of mankind; and if any one saved a life, it would be as if he saved the life of the whole of mankind. ... (Surah 5:32)

On the surface, this sounds reasonably in line with a universal code of humanitarian action and has been used to posit that very perspective. But the extension of the altruism, like with decrees in the OT, comes to an abrupt end when one reads the very next verse (not surprisingly, a verse often omitted when the previous one is cited):

The punishment of those who wage war against God and His Apostle, and strive with might and main for mischief through the land is: execution, or crucifixion, or the cutting off of hands and feet from opposite sides, or exile from the land: that is their disgrace in this world, and a heavy punishment is theirs in the Hereafter. (Surah 5:33)

It's difficult to know precisely why Hartung chose one holy book (over others) to exemplify intergroup rivalry, but he is correct in saying that this human propensity is ubiquitous and likely universal.

Realistic Conflict

In virtually every single social species studied, including ants (Shaffer et al. 2016), elephants (Plotnik et al. 2011), and vampire bats (Wilkinson 1984), selfishness is limited in order to increase the reproductive fitness of the group. The spat over group selection has been ongoing and there are few signs of feuds subsiding. In fact, heated debates over this issue have been documented between such learned individuals as E.O. Wilson and Richard Dawkins (Johnston 2014). Despite this disagreement, the evidence is clear: *genes* replicate – groups do not. However, what is also clear is that some groups thrive, while others fall into the evolutionary dustbin. In the *Extended Phenotype* (1982), Dawkins draws this analogy through the literary use of the Necker cube. At one instance, Dawkins shows, it is incontrovertible that genes replicate; however, the story can gestalt into the nearly simultaneous view that successful groups pass their genes on, while unsuccessful groups do not.

This issue is especially poignant when one considers the Israeli and Palestinian conflict. While supporters on either side feel they are unanimous, correct, and infallible, the evidence not only does not support their naive reality, it completely contradicts it. Indeed, this is exactly what the psychologist Lee Ross (2002) found when he studied in-group/out-group dynamics in these populations. He and his colleagues asked Palestinians and Israelis to draft peace proposals that were to be submitted to the “other side.” Predictably, both sides’ proposals favored their own narrative. However, before the research team reintroduced the proposals to their respective populations, they switched the names on the documents. Peace proposals drafted by Israelis that favored Israelis were entitled “Palestinian Proposals” and peace proposals drafted by Palestinians that favored Palestinians were entitled “Israeli Proposals.” Unsurprisingly, and sadly, Israelis and Palestinians rejected their own proposals that would have otherwise favored their group – simply because of the perception that it carried of the “other.”

Conclusion

Humans are by nature social creatures and it is in our nature to compete against environmental conditions as well as with one another. This has helped us not just survive – competition has helped humans achieve greatness. But as Dawkins pointed out in the *Selfish Gene* (1976), selfishness and cooperation could not have evolved independent of one another. These evolved strategies are not mere ideas painted on a blank slate. If humans are to continue to survive into the deep evolutionary future, the main out-group must not be limited to humans, but must include climate change, asteroids, and the incontrovertible finitude of our star. Carl Sagan (1994) said it best:

...every surviving civilization is obliged to become spacefaring – not because of exploratory or romantic zeal, but for the most practical reason imaginable: staying alive.

Prenatal effects of sex steroids on fertility, behavior, and health.

Introduction

John Thomas Manning (b. 1942) is best known for his work on digit ratio (or 2D:4D), i.e., the relative length of the index finger (2D) and the ring finger (4D), as a biomarker of prenatal sex steroids. He has pioneered this work by investigating relationships of 2D:4D with various measures of fertility, health, and behavior. Over the past 20 years, Manning has published numerous papers and two books that have stimulated digit ratio research in animals and humans. In addition to his work on 2D:4D, he is an expert on symmetry and has contributed a number of significant studies in humans and animals, especially on symmetry-performance relationships.

Sex and Symmetry

John Manning studied biology at the University of London (BSc) before he moved to the University of Liverpool, where he completed his MSc in Evolutionary Studies and his PhD in Zoology. He devoted a series of early scientific contributions to questions in theoretical biology related to mate selection, sexual reproduction, and the evolution of sex (e.g., Manning 1975, 1982a, b, 1984). Later he developed a strong interest in the biology of symmetry and began to investigate relationships of fluctuating asymmetry (a measure of developmental stability) and directional asymmetry (laterality) in humans and animals. Most notable of this work is the insight that asymmetry of canine size in old world primates is related to sexual dimorphism and male competition (Manning and Chamberlain 1993), and that these asymmetries are sensitive to environmental stress (Manning and Chamberlain 1994). Manning reported that fluctuating asymmetry (FA) in the legs and heads of racehorses correlates negatively with their racing ability, suggesting that FA could predict animal performance (Manning and Ockenden 1994). For humans, he reported a negative correlation of FA with body weight in men and a positive correlation in women (Manning 1995), leading him to speculate that selection pressures operate differently on male and female

size. Manning also showed that temporary, within-individual changes across the ovulatory cycle in asymmetry exist. Women were less asymmetric in mid-cycle, and this information may be used by males to assess female fertility (Manning et al. 1996).

By applying insights on FA-performance relationships in animals to similar tests in humans, Manning and Pickup (1998) demonstrated that symmetry in middle distance runners (800 m and 1500 m) indicated good running ability, i.e., symmetrical athletes had higher rankings for athletic ability. Given his considerable contributions to the study of symmetry in biology, it is not surprising that Robert Trivers teamed up with Manning and colleagues in the Jamaican Symmetry Project (JSP) to investigate long-term effects of FA on development in children (Trivers et al. 1999). The JSP has produced a number of significant findings on FA relationships with physical and behavioral correlates, including recent evidence on knee symmetry in children as a predictor of sprinting performance in adulthood (Trivers et al. 2013).

Digit Ratio (2D:4D)

Finger lengths of left and right hands are typically measured in studies that investigate relationships with a composite measure of FA, and Manning had included this trait in previous studies on relationships with, for example, male ejaculate size and sperm quality (Manning et al. 1998a). Manning and colleagues reported that the ratios of the 2nd and 4th digit length of left and right hands are sexually dimorphic (males < females), and that this dimorphism is likely established in utero under the influence of testosterone and estrogen concentrations (Manning et al. 1998b). This classic study found that in men 2D:4D negatively correlated with testosterone concentration and in women 2D:4D positively correlated with estrogen concentration. In addition, sperm number was negatively related to 2D:4D. Importantly, 2D:4D showed sex differences as early as 2 years and the values of 2D:4D and the sexual dimorphism remained relatively constant across childhood

and through puberty. Subsequent studies showed that the sexual dimorphism in 2D:4D is found across societies (although 2D:4D shows ethnic variation) and correlates with various measures of developmental health, morphology, and performance. To date, digit ratio research includes more than 700 publications stimulated by Manning's suggestion that 2D:4D provides a noninvasive measure of prenatal hormonal action.

In 2005, John Manning contributed to a large-scale web-based survey, commissioned by the British Broadcasting Corporation (BBC), designed to investigate sex differences, which collected data from 255,000 participants. With this large dataset, Manning has continued investigations of 2D:4D relationships across nations by considering national means of 2D:4D. These studies have revealed insights into prenatal hormonal effects on, for example, sexual orientation (Manning et al. 2007), handedness (Manning and Peters 2009), reproductive success (Manning and Fink 2008), gender inequalities (Manning et al. 2014a), personality (Manning and Fink 2011a), nicotine and alcohol consumption (Manning and Fink 2011b), and masculinity/femininity (Manning et al. 2017). In addition to large sample studies, Manning emphasizes that correlations of 2D:4D with testosterone- and estrogen-dependent behavior are particularly evident in studies that consider organizing effects of 2D:4D on activating effects of sex steroids (Manning et al. 2014b).

Conclusion

John Manning has contributed significantly to the study of symmetry in biology. His work on digit ratio as a noninvasive measure of organizing effects on behavior and health has stimulated numerous studies in animals and humans since the late 1990s. He has published two books on this topic (Manning 2002, 2008). The results of his recent research on 2D:4D across nations provide insight into global patterns of prenatal hormonal activity by highlighting communalities and ethnic variation in relationships with sex-dependent behavior and health.

Definition

An evolutionary biologist who pioneered the application of game theory to understand behavioral evolution across many species.

Introduction

John Maynard Smith (1920–2004) was a theoretical and evolutionary biologist, known as one of the pioneers in applying mathematical models to the understanding of behavioral evolution and diversity across many species. He developed a very early interest in natural history as a young boy and was educated at Eton before taking his first degree (Engineering) at Trinity College Cambridge, and then working on military aircraft design during World War II. He subsequently studied zoology at University College London (UCL), where he trained later as a graduate student of JBS Haldane (1892–1964) working on *Drosophila*, although he did not take his PhD as he was offered a faculty position in the same department. He left UCL to become the founding Dean of the School of Biological Sciences at the University of Sussex, retiring in 1985 but still continuing to work and publish until the later years of his life. After his death from mesothelioma, he was survived by his wife Sheila (deceased), two sons and one daughter. He was the recipient of numerous awards and fellowships, including Fellow of the Royal Society, Foreign Associate of the National Academy of Science of the USA, the Darwin, Royal and Copley Medals of the Royal Society, the Crafoord Prize, the Kyoto Prize and (posthumously), the Darwin-Wallace Award. His major books included *The Theory of Evolution* (1958), *The Evolution of Sex* (1978), *Evolution and the Theory of Games* (1982), *The Major Transitions in Evolution* (1995) (with Hungarian biochemist Eörs Szathmáry), and *Animal Signals* (2003) (with David Harper). He was influenced by, among others, the work of Charles Darwin, JBS Haldane, Ronald Fisher, and Helen Spurway. His contemporaries included George Williams, and he had robust debates with many academics including

Richard Lewontin and Steven J Gould. His exchanges and recorded interviews put him across both as an excellent debater and communicator and a kind and caring person. He published extensively (244 papers) in high profile journals including *Nature*, *Proceedings of the Royal Society of London B*, and *Proceedings of the National Academy of Sciences*, primarily with sole-authored work but also with colleagues including Brian Spratt (microbial genetics) and George Price. His work on the evolution of sex and recombination, aging and molecular evolution and population genetics were also very influential (e.g., Maynard Smith and Haigh 1974; see also Charlesworth 2004 and Charlesworth and Harvey 2005 for further discussion and personal accounts).

Major Contributions and Phenomena of Interest

The few talks and interviews of JMS preserved online at the time of writing include his interviews with writer Robert Wright in 2003 and biologist Richard Dawkins (*Web of Stories*, 1997) and his lecture *The Origin of Life* delivered as part of *The Royal Institution Discourse* in 1995. This latter talk outlined some of the key principles and ideas informing his theoretical work including one central reoccurring theme where evolution is conceptualized as the transmission of information through time via genetic and cultural means (Maynard Smith 2000). Indeed, with his colleague Eörs Szathmáry (Maynard Smith and Szathmáry 1995), he analyzed the key transitions in evolutionary history, representing changes in how information is transmitted and stored over time (see also Szathmáry and Maynard Smith 1995. Illustrated in Fig. 1). First, replicating molecules transition into populations of molecules. Next, storage transitions from independent replicators to chromosomes and then to ribonucleic acid (RNA). In a wonderful exposition of these ideas for a general audience, David Deutsch (2011) outlines how we have a catalytic process with RNA – something that promotes change in another entity while it remains unaltered, in this instance depending on the sequence of the constituent

John Maynard Smith, Fig. 1 Illustration of key transitions in evolution. Groups of molecules to chromosomes, RNA, and DNA. The first living organisms to eukaryotes, sexual reproduction, multicellular organisms, eusociality and the emergence of hominins, language, and technology.

molecules within RNA. Then, Maynard Smith and Szathmáry suggested that evolution transitions from storing information via RNA to the storage of information via DNA, which may have been due to the selective force of greater chemical stability in the latter versus the former, enabling the storage of larger amounts of information. With this stage we see a shift from prokaryote cells (meaning “before” the “kernel/nut”), related to the first living organisms Archaea and bacteria, to eukaryotes, where cells now have a nucleus enclosed within a membrane. Next, evolution transitions from asexual to sexual reproduction, followed by multicellular organisms with unlimited heredity, leading to animals, plants, and fungi where “like begets like.” These provide the conditions, eventually, for hominin evolution where a key transition in many species including our own was from individual to group living (eusociality) and the final key stage represented the transition to language in humans. With the presence of finite rules of vocabulary to convey a large number of meanings, humans in very recent evolutionary history could develop early technologies and would eventually expand their

“reach” over the planet via Enlightenment ideas, as technology combined with language enables faster cultural evolution relative to genetic evolution (see also Deutsch 2011 for further discussion). Collectively, their speculations on these issues generated much discussion within behavioral science and science more generally.

Over the latter part of his career, Maynard Smith primarily conducted theoretical work, and used modeling to explain a wide variety of phenomena including avian flight, locomotion, contest competition, female mate choice for good genes, foraging, and the population sex ratio. His debates with contemporaries were important in cementing a theoretical shift from a focus on behavior that could be considered adaptive from the point of view of the species to that which was beneficial, in Darwinian terms, from the point of view of an individual’s reproductive fitness. He illustrated these phenomena and his game theoretic models using empirical work from many different species. For example, he examined badges of status in Harris Sparrows (*Zonotrichia querula*) and Evening Grosbeaks (*Coccothraustes vespertinus*), ownership of territory and contest

competition in Hamadryas Baboons (*Papio hamadryas*), Funnel-web spiders (*Agelenopsis aperta*), Great tits (*Parus major*), and Speckled wood butterflies (*Pararge aegeria*), and the locking of antlers and vocalizations in contests for mates among red deer (*Cervus elaphus*).

Colleagues commented on JMS' exceptionally clear communication of the biology of complex systems and his commitment to public engagement with science, albeit without supervising many graduate students himself (Charlesworth 2004). In one example of his scientific writing (Maynard Smith 1978), he outlined the assumptions involved in optimization in evolution, and offers a fair and engaging response to one critic of these ideas, Richard Lewontin. In his review paper, he notes that there are constraints on what is possible in evolution. If not, to paraphrase, species would be immortal and/or invincible to predators with an unlimited capacity to reproduce (see Maynard Smith 1984). As such, we can use mathematical models from engineering and economics in order to explain biological diversity. For example, we can study the optimization of anatomical structure or skills such as foraging, reflecting a gradual process of change where different species may have evolved different solutions to an identical problem. Here, according to his argument, we can understand the selective forces responsible for the trait and form testable hypotheses based on careful assumptions. He was clear to point out that nature itself does not generate optimal solutions but traits or behaviors can have functional explanations if they are widely observed even when maladaptive – “perfect” adaptation would equate to no further evolution of that trait (Maynard Smith 1984). Models can then be revised in light of the evidence and are of use if they capture some essential feature of a complex system.

Perhaps one of John Maynard Smith's (Figs. 2 and 3) most notable achievements in his academic career was his application of game theory to explain animal behavior, using a framework originally applied to understand political conflict (von Neumann and Morgenstern 1953). Critically, however, his concept of the Evolutionary Stable Strategy solved a problem within population

John Maynard Smith, Fig. 2 Portrait used with permission by Professor Adam Eyre-Walker. (Copyright Sussex University)

genetics, by examining the behavioral strategies that prevail in a population that cannot be invaded by a rare alternative. Here, he noted that as the environment a species finds itself in is not fixed, genetic variation within different local ecologies will be frequency dependent. Put another way, traits and behaviors will vary depending on the behaviors adopted by others in the population, where the fitness of a phenotype will be contingent on the other phenotypes present (see, e.g., Maynard Smith 1982). Perhaps his most well-known model in this area is the Hawk-Dove game (Maynard Smith and Price 1973). He used this model to explain contest competition in different species, including tournaments such as the locking of antlers among red deer and displays without physical contact, where the winner is the most persistent (Maynard Smith 1974). Here, resource holding potential (RHP) and honest signals of RHP play a role in settling disputes among species, such as size and weaponry and asymmetries in other traits irrelevant to fighting outcome such as ownership of territory. The Evolutionary Stable Strategy in his models is the strategy that, if adopted by the population, cannot be invaded by an (alternate) mutant strategy under the conditions of natural selection.

John Maynard Smith,
Fig. 3 Pictured with
 Sewall Wright (1980).
 (Used with permission
 (Professor Brian
 Charlesworth))

One example of the logic from his models concerns contest competition. In simple versions of the Hawk-Dove game (Maynard Smith and Price 1973), it pays to follow a combination of hawkish and dovish strategies in competitive encounters when the costs of competition are greater than the value of the contested resource. By contrast, it pays to be a hawk if the value of the contested resource is greater than the cost of competition (Maynard Smith 1982). This game calculates the evolutionary payoff to pursuing one of two strategies and how, over several generations, hawks or doves may reproduce and proliferate within a population (i.e., the change in fitness due to pursuing a given strategy). For example, when cost is greater than reward, if one hawk or dove invades an entire population of opposites, the hawk proliferates when outnumbered by doves, as hawks can enforce costs with impunity. Doves proliferate when outnumbered by hawks, as they avoid costs to fitness by retreating and leave the hawks to inflict costs on one another (Maynard Smith 1982). Developing these classic ideas, new evidence using biological perspectives is emerging on the potential evolutionary conditions of warfare. In experiments and theoretical models, overconfidence appears to be an

important cause of warfare (Johnson et al. 2006) and this trait develops when the rewards of conflict sufficiently outweigh the corresponding costs (Johnson and Fowler 2011). Work such as this suggests that psychological mechanisms and the genetic basis underpinning different behavioral outcomes can sit within Maynard Smith's framework and motivate further work in the human animal.

Influence on Evolutionary Biology and Behavioral Science

In an interview with Robert Wright in the latter part of his life, Maynard Smith expressed some reservation about the application of evolutionary game theory to some aspects of human evolutionary psychology. Nonetheless, his concepts have influenced human ethologists and psychologists either directly or indirectly and will continue to do so. For example, his ideas are relevant to diverse topics in human behavior including physical formidability, asymmetries in male contest competition and “welfare trade-off ratios” (e.g., Puts 2010; Sell et al. 2009; Watkins 2018; Watkins et al. 2010), Darwinian medicine, human health

and aging, cues to cooperation and deception and their behavioral manifestations, facial expressions, primate vocalizations, and language as signals. A collection of essays in honor of John Maynard Smith (Greenwood et al. 1985) provides a very useful starting point for his contribution to science more generally.

Conclusions

John Maynard Smith stands as one of the primary theoreticians in evolutionary science during the latter half of the twentieth century. His mathematical models and clarity of argument helped shift focus within evolutionary biology from understanding behavior for the “good of the species” to understanding the diversity of life within specific environmental contexts. His work emphasized an understanding of how information is transmitted through evolutionary history, the structure of the population the animal is situated in and how its form and behavior within these environments suggests evidence of behavior that improves inclusive fitness. His work is important to biologist and zoologists, geneticists, and public health researchers, and his ideas are relevant to psychologists interested in human behaviors such as contest competition and mate choice in specific contexts.

Life

John Ray (1627/8–1705, known as Wray until 1670) was an English clergyman whose work in natural history led to the modern scheme of the classification of species. Born of a blacksmith and his pious wife at Black Notley in Essex, Ray studied at Trinity College, Cambridge, where he subsequently held several teaching and administrative positions. He was ordained in 1660 after flirting with nonconformity, in order to maintain his college connection (Mandelbrote 2005). Ray was a member of the newly formed Royal Society and was subsequently honored by the foundation of the Ray Society in 1844 (Fig. 1).

Ray's contributions to biology and philosophy are manifold, but the most significant ones are his contribution to the design argument for the existence of God in natural theology, and to the definition of the notion of a species, which was the first singularly biological definition.

Much of Ray's natural history work was funded directly by Frances Willughby, son of a wealthy family from Warwickshire. Willughby and Ray collaborated in both zoology and botany, although an agreement was made that Ray should focus on botany and Willughby on zoology (Mickel 1973). After traveling with Willughby, Ray moved to his estate at Middleton. Willughby died in 1672 and left a bequest to Ray that allowed him to continue his researches, as well as publishing Willughby's own research, so long as he tutored Willughby's two sons. Ray married Margaret Oakley, a member of the household, and lived at the estate.

John Ray, Fig. 1 Woodcut frontispiece of John Ray, 1693, from *Synopsis methodica animalium quadrupedum et serpentinum generis*. (Source: Wikimedia Commons, Public Domain)

After Willughby's mother, Lady Cassandra, died in 1675, Frances' widow removed her sons from Ray's care and effectively ejected him and his wife from the household. They moved back to his birth village and he remained there until his death. He had four daughters, who aided his research when they were older.

Natural Theology

Ray's most widely read work was his *The Wisdom of God Manifested in the Works of Creation*, which he published at 64, just 4 years after Newton's *Principia* (Ray 1691; Berry 2011). The book was a revision of sermons and talks

he had given over 20 years earlier while at Cambridge and forms one of the major foundations of the rise of natural theology, in which the existence and nature of God is derived from the “book of Nature” rather than the book of revelation. One of the other major initiators was Robert Boyle, whose essays on reason and religion suggested that the empirical turn in natural history was appropriate for people of faith (Gillespie 1987). Unlike Newton’s later posthumously published writings on scripture, Ray was quite orthodox in this work.

However, Ray had to justify natural history as something that could be adopted faithfully. He asserted that “to contemplate the works of God is part of the business of a Sabbath-day” (Ray 1691, p. 124). Arguably, his success in this respect made natural history popular with the leisure classes, and so added to its growth in popularity over the subsequent decades. This generated a popular and learned tradition of doing theology through natural history in the British tradition.

Ray was convinced that everything had a purpose – if not a human purpose, then a divine one (Berry 2011, 329f). But he did not insist, as his contemporaries (such as Gilbert White) tended to, that all of nature was provided by a beneficent deity for humans:

It is a generally received opinion that all this visible world was created for Man [and] that Man is the end of creation, as if there were no end of any creature but some way or other to be serviceable to Man . . . But though this be vulgarly received, yet wise Men nowadays think otherwise. (Ray 1691, 127f.)

According to Berry, Ray held these “physico-theological” views at the very beginning of his scientific career, in the 1660s. These views led to the rise of natural theology leading directly to William Paley’s *Natural theology* in 1802, which was in turn influential upon Darwin’s early investigations.

Wilkins and Linguistics

Bishop John Wilkins’ *An Essay Towards a Real Character and a Philosophical Language* (1668, 2002) was an ambitious project to classify not

only all organisms but all ideas (and it was the foundation for Phillip Mark Roget’s *Thesaurus*). In reviewing the contributions of Wilkins, Ray, and Linnaeus to the history of systematics, Stearn (1986, pp. 111–113) wrote:

The botanical tables prepared by Ray for Wilkins had to fit the latter’s formal prescribed scheme, i.e. herbaceous plants had to be divided into three groups as nearly equal as possible, these then divided again into nine groups and the species then in pairs. So artificial a classification was inevitably unsatisfactory from a botanical standpoint; indeed, only a botanist with Ray’s detailed knowledge of plants and his obliging nature would have had the ingenuity and kindness to construct one at all.

He contracted Ray to do the species lists, but, as Stearn notes, had a very rigid logical schema into which these tables (indented lists with braces) had to fit. This garnered significant criticism from Robert Morison (1620–1683), Professor of Botany at Oxford, who both attacked the artificiality of Wilkins’ scheme and claimed that Ray had plagiarized his own work (Stevenson 1947, p. 253). Ray was stung by this, being still very junior in botany, and thus began his careful and systematic method of classifying and enumerating species of plants. (Sloan (1972) gives a good account of both the results of Wilkins’ strictures and the reactions of Morison and Rivinus.)

Wilkins’ system was part of what has come to be known as the Universal Language Project (Wilkins 2018, Chap. 4), and Ray and Willughby contributed somewhat, under the influence of Ralph Cudworth and the Cambridge Platonists. Ray published *Collection of English Words Not Generally Used* (1674) and *Trilingual Dictionary, or Nomenclator Classicus* (1675) (Cram 2016). More to the point, Wilkins used the standard Latin terms for inclusive and included groups of things, *genus* and *species* (roughly equivalent to our “set” and “subset”), and thus Ray was forced to refer to living things as species in genera. This was not original to him, as Bauhin had used it much earlier, given that both the terms were “vernacular” in academic Latin, and the Aristotelian logic was common to the educational curriculum of the time, but it led directly to his defining, for the first time, a purely biological notion of species.

Species and Systematics

Ray's greatest claim to fame is his work in botany, and in particular his publication first of a flora of Cambridgeshire, and then of Britain, starting a tradition of florae in botany. Subsequent to these works, he published the *Historia Plantarum* in 1686, with volume 2 in 1688. (The former in 1660, *Catalogus Plantarum circa Cantabrigiam nascentium*, the latter in 1677, *Catalogus Plantarum Angliae* (Lankester 1846, pp. 111–113).) His *Methodus Plantarum Nova* (Ray 2015, second edition 1703) introduced the distinction between monocotyledons and dicotyledons, although he also retained much of the older Aristotelian classification of plants as herbaceous, woody (ligneous), and so on.

In the *Historia Plantarum*, Ray wrote:

In order that an inventory of plants may be begun and a classification of them correctly established, we must try to discover criteria of some sort for distinguishing what are called “species.” After a long and considerable investigation, no surer criterion for determining species had occurred to me than distinguishing features that perpetuate themselves in propagation from seed. Thus, no matter what variations occur in the individuals or the species, if they spring from the seed of one and the same plant, they are accidental variations and not such as to distinguish a species. For these variations do not perpetuate themselves in subsequent seeding. ... But variations that never have as their source seed from one and the same species may finally be regarded as distinct species. Or, if you make a comparison between any two plants, plants which never spring from each other's seed and never, when their seed is sown, are transmuted one into the other, these plants finally are distinct species. For it is just as in animals: a difference in sex is not enough to prove a difference of species, because each sex is derived from the same seed as far as species is concerned and not infrequently from the same parents; no matter how many and how striking may be the accidental differences between them; no other proof that bull and cow, man and woman belong to the same species is required than the fact that both very frequently spring from the same parents or the same mother. Likewise in the case of plants, there is no surer index of identity of species than that of origin from the seed of one and the same plant, whether it is a matter of individuals or species. For animals that differ in species preserve their distinct species permanently; one species never springs from the seed of another nor vice versa. (Ray 1686, Vol. I, 40, Trans. Edmund Silk. Quoted in Beddall 1957, pp. 133–134)

While *species* had been used routinely in natural history to denote kinds of living beings, Ray's is the first definition of the term that applies solely to living things (in contrast to species of minerals, etc.), and his definition relies upon (i) reproduction or generation (propagation through seed) and (ii) similarity of progeny to parents and pace sexual differences. In this respect he formalizes the practice of the past century of botany and zoology, but he also indicates operational tests for specificity and for distinguishing between varieties and species. I have called this traditional sense of living species *the generative notion of species* (Wilkins 2018).

Moreover, he denied that species were mutable, and that they would go extinct, or at least that we could know this (Lankester 1846, pp. 207–214). He rejects the variation in species as evidence of new species, ascribing it to changes in climate, etc., which are “accidental differences.” As to extinction, he asks:

whether . . . any species lost or destroyed? To which I answer, 1. That though it is absolutely and physically possible, yet it is highly improbable, that any species should be lost. 2. Though some species should be destroyed, yet it is impossible morally that any man should be sure thereof.

It is unclear if he thought this because of some adherence to the principle of plenitude – that God would fill the world with all kinds that he could and would not permit them to be lost. In *Wisdom*, he held that no new species would be produced by spontaneous generation, which he rejected, but he also allowed that fossils were remnants of species. His argument depended upon the principle “Nature makes nothing in vain” (*Miscellaneous Discourses*, 1692). Hence no fossil teeth, bones, or leaves would be made unless they were remnants of past organisms. Nevertheless, he still thought they might live in some other part of the world, such as deep oceans. He objected that the loss of species out of the world:

which Philosophers hitherto have been unwilling to admit, [meant] esteeming the destruction of any one Species a dismembering of the Universe, rendering it imperfect: whereas they think the Divine Providence is especially concerned to secure and preserve the Works of Creation. . . . (Ray 1692, p. 119)

Influence

The extent of the influence of the genius of Ray on the science of natural history is far greater than can be estimated by the number or size of the volumes which he wrote, and is to be traced to his habit of acute observation of facts and the logical accuracy with which he arranged them. He made his knowledge of the structure and physiology of plants subservient to a great plan for their arrangement, and this plan, when carefully examined, will be found to contain the fundamental principles of all the more recent scientific systems in natural history, and to have laid the foundation of the views of a natural classification of the vegetable kingdom put forward in later times. (Lankester 1846, pp. viii–ix)

Edwin Lankester's estimation of Ray's importance in 1842 was not retained in the era after Darwin, despite his influence over those who preceded Darwin and Darwin himself. In botany, Ray established some of the basis for Linnaeus' classification of plants and was inclined to use empirical methods first and foremost in describing species. In natural theology, his *Wisdom* set the tone and many of the arguments that resulted in the later examples of that genre. But his greatest contribution remains as critical today as when he first made it: the biological definition of *species*. It is at once a traditional definition, one that later influenced Cuvier and established the fixity of species as a viable and perhaps only orthodox view until the end of the eighteenth century and also one that at its base is still employed by systematists: a species is a lineage of reproductive linkages that tend to produce progeny that closely resemble their parents. This is the prior meaning of "common descent" that Darwin employed later.

► Founders of Evolutionary Psychology

John Turner

Jody A. Thompson
 University of South Carolina – Beaufort,
 Bluffton, SC, USA

Definition

An influential British social psychologist and Professor of Psychology at Australian National University in Canberra.

Introduction

John Turner was born in South London to a -working-class family which lived in a small council flat. He was the son of a construction worker and the firstborn of eight children. At the age of 11, he received a scholarship to attend Wilson's School in Camberwell – a boys' grammar school. His working-class accent differentiated him from his more conventional middle-class peers. He received his Bachelor of Arts Honors in Social Psychology at University of Sussex in 1971. Under the tutelage of Henri Tajfel, he received his PhD in Social Psychology from the Bristol University in 1975. He continued at Bristol University as a research associate and lecturer after earning his doctorate. He spent 1 year at the Institute for Advanced Study at Princeton from 1982 to 1983 and then moved to Macquarie University in Sydney. In 1990, Dr. Turner moved to the Australian National University in

Canberra. In 1999, he was awarded the Henri Tajfel Memorial Medal by the European Association of Experimental Social Psychology (Reicher and Haslam 2011; Haslam et al. 2011; Bourhis 2012).

Career and Contributions

While an undergraduate at University of Sussex, Turner worked at a printing factory. During this time, he gained experience as a trade union organizer and started noticing how collective action could nurture a sense of in-group belongingness, group unity, and pride in one's group. At Bristol University, his advisor had noticed that once people created groupings, they tended to emphasize the similarities of themselves within their in-groups and the dissimilarities of themselves from groups of which they do not belong (Tajfel and Turner 1979; Turner 1999). Together, Turner and Tajfel developed *social identity theory*. This theory asserted that people have a strong tendency to categorize themselves into groups in order to gain a greater sense of who they are; consequences for these categorizations play a role in self-esteem for the individual and prejudice and stereotyping for those that belong to other groups.

John Turner is also credited with the formation of *self-categorization theory* – which describes the circumstances in which an individual will recognize groups of people, themselves included, as a group (Haslam 1997). A major principle of the theory is that one should not consider the self as a foundation to cognition but that the self is actually a product of our cognitive system (Turner and Onorato 1998; Turner et al. 1994; Reynolds and Turner 2006). Self-categorization theory has been applied to topics such as social influence, group polarization (Turner et al. 1987), outgroup homogeneity, power (Turner 2005), and leadership (Haslam 2001; Haslam et al. 2011b).

In his book *Rediscovering the Social Group* (1987), he explored the connection between the individuality of the person and the social reality of the group identity. He found that when humans

view others as “us” instead of “them,” people will be motivated to help or work with these other individuals. He described that working together with a shared identity is vital to our future.

Conclusion

Dr. Turner died on July 24, 2011. He was a captivating figure who attracted students to both his research and his causes. His contributions include the development of two key theories regarding individuals acting as group members. He was also quite knowledgeable in politics. He has left a lasting impact on social psychology through not only his research but also through his students. His former pupils have gone on to occupy senior positions around the globe.

John Watson

Polyxeni Georgiadou
University of Nicosia, Nicosia, Cyprus

Synonyms

Behaviorism

Definition

Well-known psychologist, founder of Behaviorism.

Introduction

John Broadus Watson (1878–1958), a comparative psychologist, is considered as the person who tried to divert researchers' attention from introspection toward a behavioral understanding of the world, and he was the first who introduced the term "Behaviorism" (Rakos 2013). He was a proponent for the use of scientific approach to examine everyday phenomena (Bakan 1960), a strong supporter of the importance of environmental factors in influencing behavior (Morris and Todd 1999), and an advocate for the use of research findings to reduce or eliminate social problems (Bakan 1960). His hard work, his passion for his beliefs, and the innovations he brought to research stirred up a lot of controversy even long after his death (Horowitz 1992).

His Personal Life

John Broadus Watson, born and raised in the village of Travellers Rest in South Carolina, was the fourth of six children, growing up in a financially underprivileged family. His father, Pickens, was a civil war veteran with a strong preference for alcohol and women. Pickens was close to his son John while he was growing up and he taught him how to master various masculine skills and interests such as handling tools, managing a farm and its equipment, and carpentry, interests he kept throughout his life. His mother, Emma, a devout Baptist who held an active role in the Baptist Church, strongly urged her son to become a minister (Hergenhahn 2000; Moore 2017). Despite her husband's lifestyle that strongly opposed to the Baptist's beliefs, Emma was trying to hold the family together and at the same time to instill to her children her love for the church and her belief in professional advancement through education (Morris and Todd 1999). The family moved to Greenville in 1890 with hopes for greater financial opportunities, but this move brought an extra strain to the marriage and resulted in Pickens leaving the family for good in 1891, when John was 13 years old. Pickens departure was very painful

for John who never forgave his father and resulted in an adolescence of great rebelliousness, where he became disinterested for his studies and engaged in frequent fights with others (Hergenhahn 2000; Morris and Todd 1999).

John managed to graduate from high school even though his academic record was not superior, and he realized that academic education would offer him the means to follow a profession that would provide better living circumstances. At the age of 16, he succeeded in getting accepted at Furman University, a small Baptist college in Greenville (Morris and Todd 1999). At Furman, he studied philosophy and psychology, from where he graduated 5 years later earning a master's degree in 1899. Despite his degree, he was living poor and with few friends and, in addition, at 1900 his mother Emma became ill and died. Wanting to pursue further studies, and with the support of one of his philosophy professors from Furman University, he enrolled at the University of Chicago to study philosophy. He arrived at Chicago with almost no financial resources and he had to work simultaneously different jobs as a waiter and at the psychology laboratories in order to survive (Hergenhahn 2000).

During his graduate studies, Watson pursued a major in experimental psychology supervised by Angel, a first minor in philosophy supervised by Dewey and a second minor in neurology supervised by Donaldson. The intensive studies along with his hard labor work to support himself financially led him to a state of exhaustion which he managed to overcome, and eventually completed his dissertation in 1903 (Moore 2017). In his dissertation, he studied whether myelination in the rat's brain obstructed rat's ability to perform complex behavior, especially maze learning (Moore 2017).

After receiving his Ph.D., Watson accepted a position as an instructor in University of Chicago, where he taught experimental psychology and continued his research with the rats in his laboratory. He met and married Mary Ickes, one of his students, daughter of a prominent Midwestern family. John and Mary had two children together, Mary (born in 1905) and John (born in 1908). The Icke's family never approved of Mary's marriage

to John, whom they thought was a gold-digger (Moore 2017).

In 1907, Watson accepted an offer for the position of full professor at John Hopkins University, one of the most prestigious Universities of America, and soon after he stepped up in the hierarchy, a move that further increased his developing reputation (Moore 2017). The research he was developing at Hopkins on the conditioned reflex process in rats was interrupted in 1917 because he joined the US Army during World War I. In the army, he worked on screening aviators and studying the effects of oxygen deprivation on their skills until 1918 when the war ended and he returned to the academia describing his experience in the military as highly dissatisfactory (Watson 1936, as cited in Moore 2017).

His return from the army and back to Hopkins marked a shift in his research interest. He began studying human development, especially child development from a behavioristic point of view; he studied the conditioned reflex and the conditional emotional reactions of children that led to his famous study on Little Albert (Watson and Rayner 1920, as cited in Moore 2017).

His assistant in this new turn of his research was another student of his, Rosalie Rayner, a lively and beautiful young woman of a wealthy and prominent Baltimore family, with whom John got romantically involved (Hergenhahn 2000). This extramarital affair was the “last straw” of a marriage already shaken by different problems (Moore 2017). Mary and her family – who always disapproved of Watson – got so enraged with his love for another woman while still legally married that used all their social and financial power to pressure the John Hopkins Administration to fire Watson. Hopkins University, in turn started pressuring Watson who, finding no support from any of his former colleagues and friends, resigned from Johns Hopkins in October 1920 (Moore 2017).

Unemployed and with no support, and while his divorce was pending, Watson went to New York and accepted a job in J. Walter Thompson advertising company, thus marking the beginning of a new chapter in Watson’s life and career in business (Moore 2017).

The Ickes family insisted on embarrassing Watson further by initiating formal divorce proceedings and publishing articles about the divorce in newspapers. Watson’s divorce from Mary was finalized on December 24, 1920, and he married Rosalie on December 31 (Moore 2017); he was 42 and she was 21 at the time. Rosalie and John had two sons together, William (born in 1921) and James (born in 1924).

Watson’s success in the world of advertising led him to the position of Vice President of J. Walter Thompson in late 1924, while he continued to give lectures in New York. John and Rosalie continued to study and share their views on childrearing with the public until Rosalie’s death in 1935 of dysentery, at the age of 36. Although devastated from Rosaline’s death, John continued his advertising career by leaving Thompson in 1936 for the position of Vice President at William Esty, another advertising company, until his retirement in 1945. In the early 1950s he moved to a small estate in Connecticut, where he spent his last years devoted to his land, his animals, and drinking excessive amounts of alcohol. He died in 1958 at the age of eighty of cirrhosis, only a year after he was awarded (in 1957) the Gold Medal by APA for his significant contributions to psychology (Hergenhahn 2000; Moore 2017).

The Precursors

A number of different academic, cultural, and personal factors prepared the soil for Watson’s theory and research and led to the need for a more objective psychology: (a) modern philosophy and Rene Descartes’s attempt to bring together the mind and the body; (b) Wundt’s methods of studying in the first psychology laboratory in 1879, and (c) the evolution of biology and neuroscience. At the same time, the changes in American culture toward the increase of technical knowledge, institutional control, and industrial development became the cornerstone into building a nation based on science, technology, and progressivism (Morris and Todd 1999). Watson, although not prepared by his poor rural family to survive in this new way of living, soon realized that in order to survive successfully in a

progressive culture, university education and a profession, and in particular psychology, could generate the means (Buckley 1989 as cited in Morris and Todd 1999).

Before Watson, research in psychology was monopolized by the concept of “consciousness,” that is, the examination of conscious processes and their analysis through language (Malone 2017). Instead, Watson proposed to study psychology in an objective way by concentrating on behavior, thus making it an objective science (Moore 2011; Todd 1994). He claimed that by restricting research on “introspection” and on training people to examine their conscious experience on predetermined subjective labels, we eliminate our field of study only on sane humans who are able to understand and use language, at the same time excluding children and other individuals who lacked the ability to communicate, people with psychopathology, and subhuman animals (Malone 2017).

The Beginnings of His Career: The Birth of Behaviorism

When Watson entered University of Chicago in 1900, he found academia in a process of change (Buckley 1989, as cited in Morris and Todd 1999). He began studying philosophy under Dewey but turned his attention toward Angell’s functional psychology who encouraged him to describe and analyze behavior. This led to a career in comparative psychology, a field of studying the behavior and evolution of different animals, at the laboratory and outside of it as well, and this area became the topic of his research for years. Between 1903, where he received his doctorate, and his 1913 famous Columbia lectures, Watson studied the importance of the sensory system for learning in rats; he conducted field observations on birds’ homing abilities (Tinbergen 1951, as cited in Malone and García-Penagos 2014) and successfully designed equipment to assess the visual capacities of nonhumans, all significant steps for the assessment of nonhuman perception (Boakes 1984).

In Watson’s agenda, the results from the study of comparative psychology could be equally applied to humans, since throughout his life he

strongly believed that the behaviors of humans and animals had no essential differences except from the use of language (Malone and García-Penagos 2014).

During his work as an experimentalist Watson equipped two animal laboratories, designed complicated apparatus, and carried out pioneering experiments on rats, birds, monkeys, and human babies, attacking multiple problems related to neurological developments of different species, instincts and performances, and the early emotional development of the human child (Dewsbury 1994).

Watson’s Career After 1913

By 1913, Watson was professionally established, had a big reputation as a scientist, published more than 65 articles and reviews, and had attained significant professional status (Buckley 1989, as cited in Morris and Todd 1999). He concluded that for psychology to become a science, it had to produce observable results, much like other sciences, at the level of behavior, and it had to become popular (Morris and Todd 1999). His strong beliefs about examining behavior as the only scientific method and his introduction of the term “behaviorism” awarded him the fatherhood of the term, and despite strong arguments against it, he managed to make behaviorism an established entity (Logue 1978; Woodworth 1959).

Watson’s 1913 publication of “Psychology as the Behaviorist Views It” (Watson 1916), taken from a lecture delivered at Columbia University, was later referred to as the “Behaviorist Manifesto” for its innovation and forceful tone that launched the “Behavioral revolution” and signified behaviorism as a separate orientation in psychology (Moore 2017). Even though at the time the impact of that publication was not significant (García-Penagos and Malone 2013), it was later judged as “the single most important publication in the 50 years of the *Psychological Review*” (Langfield 1943). In that publication, Watson presented the three main features of his theory. First, he emphasized the importance of using observational and experimental analyses in order to predict and control behavior, stressing the role of the

environment in human development and criticizing conclusions made about heredity. Thus, he presented psychology as a natural science aiming to predict and control behavior, with an emphasis on environment as a determinant of behavior (Logue 1994; Watson 1913). Furthermore, beyond promoting the concept of learning he argued that scientifically validated behavioral principles could be applied to a variety of social needs and problems, such as education, advertising, psychotherapy, in order to improve society and make life better (Hart and Kritsonis 2006; Salzinger 1994; Samelson 1981). Second, he rejected consciousness, mind, and image as the subject of psychology and took the position that consciousness did not exist as an entity (Morris and Todd 1999; Watson 1913b). Instead, he argued that there is no such a thing as “mind” because it is an abstract concept. There are activities like seeing, hearing, listening, remembering, and imagining, but they do not constitute a “mind” that is separate from the body. Thus, the mind/body distinction is a false one (Malone 2017). His rejection of consciousness and the mind resulted in a confusion as to whether he was a methodological or metaphysical behaviorist or, as Skinner later named it, “radical behaviorist,” a term that “holds that mental terms are fictional products of folk psychology and that the mind/body distinction is a false one” (Malone 2017, p. 4).

Third, he addressed the activities historically associated with consciousness and mind, namely, thinking, feeling, and imagining in a behavioral manner. Thus, he developed the theory that thought processes are motor habits in the larynx, emotions in the glands, and imagery in the movements of the eye (Watson 1913). For him, learning was part of the organism’s interaction with the environment, even though a sometimes private but real environment (Morris and Todd 1999). The 1913 manifesto was the first clear conflict with other approaches and the first to argue for the use of empirically derived principles with the aim to improve society (Rakos 2013).

From Animals to Humans

Until 1916 Watson worked exclusively with animals influenced by the Darwinian thought in the

evolution of the species and believing that human behavior could be explained sufficiently by the examination and explanation of behavior of non-human organisms (Logue 1978; Malone and García-Penagos 2014). In 1917, he switched into postulating that human beings might have unique instincts, different from those of lower organisms, and thus, generalizations from studies on animals to humans was not a safe practice (Logue 1978; Todd 1994).

In his book *Psychology From the Standpoint of a Behaviorist* first published in 1919 (1924, 1929), he asserted the following basic principles. First, he recognized that the human body was a complex organismic system integrated with the behavioral system. Second, although he acknowledged the role of structural change, he clearly postulated that learning was almost exclusively responsible for behavioral development. Third, he insisted on the need for developmental research examining infants, the role of their emotions, and the principles of their learning, by using the experimental method (Horowitz 1992).

Watson identified five categories of objective methods and procedures for psychological research: (a) systematic observation available for analysis through descriptive statistics; (b) conditioned reflex method, as used by Pavlov (1906, as cited in Morris and Todd 1999); (c) verbal reports of implicit and explicit responses and stimuli; (4) standardized testing, and (5), social experimentation (Morris and Todd 1999).

Organization of Behavior

Watson’s organization of behavior included three main categories depending on (A) the origins and loci of behavior (Formal Organization), (B) function (Functional Organizations), and (C) natural-language categories. In “Formal Organization” of behavior, he presented: (1) the distinction between heredity responses (i.e., instinctive, such as reflexes or emotional, such as love, fear, and rage) and habits (i.e., learned responses); (2) whether behavior was explicit (e.g., reading) or implicit (e.g., mental counting); and (3) whether it was manual (e.g., eye-hand coordination), laryngeal (e.g., talking aloud), or

visceral (e.g., emotional reactions) (Morris and Todd 1999).

In *Functional Organization*, although he identified 6 determinants of behavioral regulation, it was the determinants of: (a) recency, the most recent response to stimulus; (b) frequency, the most frequent response to stimulus; and (c) the response most closely connected to the overall situation or context (e.g., responses appropriate for one context but not for another) that he emphasized the most (Morris and Todd 1999).

In his classification of behavior in terms of natural-language categories, he included categories such as emotion; manual, motor, or bodily habits; language; thinking; memory; work; and personality (Morris and Todd 1999).

Reflexes and Habits

While at Chicago University (early 1900s), Watson was studying the sensory modalities that underlay maze learning in rats, as well as the various “instinctive” behaviors of sea birds. Although he got confusing results, the most crucial was that instinctive behavior is not static; it develops through interaction with the environment and takes its different forms according to relevant environmental stimulation (Watson 1914, in Moore 2017). Progressively, Watson was influenced by Pavlov’s ideas on conditioned reflexes and adopted the same views, to the extent that after his election as president of the American Psychological Association in 1914, his presidential address in 1915 was on “The Place of the Conditioned Reflex in Psychology” (Watson 1916, cited in Moore 2017). He postulated that the organism is comprised of a large number of reflexes, or unit acts, that, although they may vary depending on heredity, they “can be shaped” depending on the environment. The organism selects and eliminates the useless movements; thus, with the constant selection of the correct movements, habit formation develops in the service of adjustment. A number of simpler “reflexive” units selected by the environment compose a much larger unit that form a “response.” He believed that the principles of frequency and recency account for simple habit formation (Malone and García-Penagos 2014). Specifically,

he discussed how stimuli that did not instigate a response can do it later indicating his recognition of the complexity of human behavior (García-Penagos and Malone 2013). Progressively, he attributed more importance in the concept of conditioning in his theory. Specifically, he considered conditioning as the mechanism by which words come to be integrated into habit systems, and eventually, he used his same ideas about the conditioned reflex to explain all other habits, which were now defined as “a series of conditioned reflexes.” For him, conditioning could explain how habits are formed, maintained, and rejected (García-Penagos and Malone 2013).

Today this viewpoint is known as *classical S–R behaviorism*. He used the terms *Stimulus* meaning any general environmental situation or internal condition of the organism, and *Response* as anything the organism did (Horowitz 1992). This approach in research represented the first phase of the “behavioral revolution” and was very popular until it was recognized as inadequate and researchers inserted “organismic” variables between stimulus and response as a way to mediate this relation (Moore 2011).

Thus, the principal unit of analysis for all the studies of Watson was the “habit,” defined as “the coordinated and consistent act that develops in a given situation through repetition, rather than some supposed phenomenon from mental life” (Moore 2011, p. 451).

Watson further devoted his professional attention on conditioned reflexes on behaviorism and established it as the main orientation in psychological science at the time upon his return to Hopkins after the end of his military service to World War I (Moore 2017).

The end of the second decade of the twentieth century found Watson in the laboratory turning his attention to human behavior, and particularly to child development. He proposed 3 basic emotional responses for human infants: (a) fear, caused by loss of support or sudden sounds, (b) rage, caused by restricting an infant’s movements, and (c) love, caused by stroking the skin, especially in sensitive erogenous zones. He suggested that through conditioning, the emotional responses produced by different stimuli

expand throughout life and account for the diversity of human development, a position he tried to prove through his famous experiment with Little Albert, his last formal research in academia (Moore 2017).

In 1920, even after the end of his academic career, he continued giving lectures at local universities that resulted in his popular book “Behaviorism” (Watson 1925, cited in Moore 2017) where he incorporates the data from different studies before Little Albert in a book about child rearing (Moore 2017).

On Environmentalism

Watson was identified as a strong environmentalist. Up until 1917, he was holding a middle ground on the power of heredity and environment in development. Progressively, as he came to believe that the differences between species were too large to allow any conclusions from one species to another, he came to adopt the position that eventually environment is responsible for change (Morris and Todd 1999). This shift became prominent in his 1924 book on “*Behaviorism*” where he stated that humans have only a small set of instincts compared to animals, and he narrowed the concept of emotions in only three responses: fear, rage, and love (Rakos 2013). For him, genetics were responsible for the prevalence of instincts in nonhumans and the relative lack of them in humans. Furthermore, although he acknowledged that physical characteristics are inherited, he did not say the same about “mental traits” (Rakos 2013). In one of his most famous and frequently quoted statements, he says:

Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select – doctor, lawyer, artist, merchant, chief and, yes, even beggarman and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors. I am going beyond my facts and I admit it, but so have the advocates of the contrary and they have been doing it for many thousands of years. (1924/1970, p. 104) (Logue 1978)

In the last three lines, not usually quoted, it shows that what appeared as an extremist environmentalist position was a result of his effort to

counteract the equally extremists hereditarian psychologists of the time who, according to him, had based their views mostly on prejudice rather than scientific analysis (Logue 1978; Todd 1994). Thus, although Watson's position on the heredity versus environment dilemma progressively changed, it was only in 1924 in “Behaviorism,” 4 years after the termination of his academic career, that this division was emphasized.

In conclusion, Watson asserted that the organism's inherited biological structure interacts with the environment to produce behavior. Any change on any of those factors (i.e., biological structure or environment) through learning, injury, etc., changes behavior (Morris and Todd 1999).

Application of the Principles of Behaviorism on Child Rearing

After the end of his academic career from Johns Hopkins, Watson continued only with the studies conducted by his supervisee, Mary Cover Jones (1896–1987) on the elimination of children's fears (Jones 1924a, b, as cited in Morris and Todd 1999), a continuation of his studies on “Conditioned Emotional Reactions” (Watson and Rayner 1920, as cited in Morris and Todd 1999), both studies now considered a landmark in the history of behavior therapy (Krasner 1988).

Watson's interest on children began in 1916 where he studied, along with his wife, their emotional development. Results of his infant studies led to a number of books and publications as well as popular articles in magazines. They concluded that the root of adult psychological problems lies in childhood, and especially in too much pampering. As a result, they suggested treating the child as an adult. Any forms of emotional display (i.e., kissing and hugging) needs to be eliminated in order to reduce conditioned emotional reactions. They further encouraged parents to promote greater self-sufficiency to their children, to be honest and open to them, and to abstain from any form of corporal punishment (Morris and Todd 1999).

Watson and Advertising

At the age of 42, Watson turned his attention to advertising. He used the behavioral approach in

advertising and launched a very successful second career, by using his findings on infants' innate emotional reactions on how to attract the viewer's attention. Furthermore, he used behaviorism principles in personnel selection and management (Malone 2017).

Watson on Psychopathology

Watson approached the concept of psychopathology through his belief about adjustment. He postulated that we go through life adjusting to the different situations by producing a set of reactions organized in a way to help us adjust into new situations. When new circumstances we encounter in life resemble old, familiar ones, the adjustment is easier. The adjustments we learn through life become our personality, and a well-adjusted personality can deal with new situations. Psychopathology develops when new situations are so novel that the person is unable to adjust because it would mean to break up the present habit patterns. This novel situation can cause a trauma, and recovery from trauma, although possible, can be difficult and lengthy since it requires personality restructuring (Malone 2017).

Watson as a Person

John Watson was considered to be a controversial man (Horowitz 1992). He was disciplined, articulate, straightforward, and self-assured; he kept close and long friendships with Titchener and Angell, while also his second marriage was successful (Brewer 1991; Morris and Todd 1999). Furthermore, he was considered attractive, strong, and scientifically accomplished. For others, Watson was arrogant, rigid, and unreflective (Brewer 1991; Horowitz 1992; Morris and Todd 1999).

Memories of his son James present Watson as having a sense of humor, charming, bright, sociable (yet shy), fastidious, and masculine. He was concerned with manly activities, courage and personal capabilities, and manual work. Yet, he was afraid of the dark and of driving (Hergenhahn 2000). He displayed more affection for animals than for people including his children. According to James, the lack of warmth and affection by his father was the reason for the lack of the self-

esteem necessary for a healthy life that led to his brother's suicide. After Rosalie's death in 1936 Watson changed; he was devastated and seemed "confused" and depressed for several years (Malone 2017; Moore 2017).

Conclusion

John Broadus Watson appears to be one of the most controversial researchers in the psychology of twentieth century. He is known as the person who used innovative methods in examining animal behavior and specifically learning. Early on in his career, he challenged the subjects and the methods of studying humans in psychology of the times. He is most known as the person who emphasized the importance of examining behavior and for this reason the term "behaviorism" was attributed to him. Even though his research on humans is limited, his writings are being examined for decades long after his death and have influence in research and practice in psychology.

Definition

Jonathan Haidt is a psychologist best known for his work on moral psychology.

Introduction

Most of Jonathan Haidt's work has focused on moral psychology. His first major contribution to the field was the Social Intuitionist Model of moral judgment. This model posits that, unlike the assumptions of many previous philosophers and psychologists, moral judgments were not conscious, logical processes, but instead the product of multiple automatic processes (Haidt 2001). Other major contributions include his work on developing a scale of moral disgust and moral elevation. More recently he continued work on his Social Intuitionist Model, expanding it to cover the most important categories of moral intuition. This new model was called the Moral Foundations Theory.

The Social Intuitionist Model

The Social Intuitionist Model proposes four specifics of moral judgements: Moral judgements are primarily intuitive, justified after the fact, created to influence others, and influenced by others. This theory differs from previous theories by positing that humans do not come to moral judgements in a rational way, but that they come to moral decisions based on intuition and then

later find information to justify these judgements. This conclusion was drawn after research on moral dumbfounding demonstrated that humans will frequently come to very strong moral reactions without being able to justify their reasoning. The most common scenario demonstrating this involved siblings that slept together once. No one knows they slept together, no harm comes to anyone, protection is used, and it makes them feel closer. Most people have very strong negative reactions to this scenario, but are unable to rationally justify why other than by appealing to a belief that incest is bad as a rule (Haidt 2012).

Moral Disgust and Elevation

Haidt, along with others, developed a widely used scale of moral disgust. The scale is designed to measure individual differences in disgust sensitivity (Haidt et al. 1997). They argue that disgust evolved to protect the body from pathogens which enter through the mouth and later was expanded through cultural evolution to protect social and moral order. Research into moral disgust led Haidt to examine moral beauty, also termed moral elevation. Moral elevation was illustrated by Algoe and Haidt (2009) who exposed participants to stories about moral beauty that causes common sets of responses such as a desire to be a better person, calmness, and loving feelings. Further research demonstrated that feelings of moral elevation could cause breastfeeding mothers to lactate (Silvers and Haidt 2008), drawing a possible connection between moral elevation and the hormone oxytocin.

Moral Foundations Theory

Moral Foundations Theory was produced as an extension of the Social Intuitionist Model through collaboration with many authors (Graham et al. 2012). This theory states that human morality is derived from five major moral domains, or foundations: care/harm,

fairness/cheating, loyalty/betrayal, authority/subversion, and sanctity/degradation. These foundations are the product of specific mental modules evolved to solve recurrent problems for our ancestors. The presence of each of these modules would have functioned to solve common problems for our ancestors, such as caring for children (care/harm) or avoiding pathogens (sanctity/degradation).

Conclusion

Throughout his career, Jonathan Haidt is best known for his development of the Social Intuitionist Model and his work on Moral Foundations Theory. These two models have fundamentally changed how many in social psychology view moral psychology and provide one of the most comprehensive examples of an evolutionarily informed approach to moral domains.

Definition

Jonathan Haidt introduces moral foundations theory in his book and tries to challenge the way we think about the origins of political differences and good and evil.

Introduction

Haidt's *The Righteous Mind* consists of three main chapters. In the first part, he argues that moral judgments are realized through intuitive thinking based on the social intuitionist approach. In the second part, some theoretical approaches based on harm and justice are criticized and it is claimed that morality corresponds to more than harm and justice. In the third part, it is argued that morality is intertwined with (in particular, religious) group behavior and that moral intuitions underlie our group psychology and political differences.

Haidt (2001) endorses the Humeian point of view on morality and criticizes Kohlberg's rationalist moral understanding based on Kant's moral philosophy. According to Kohlberg's rationalist perspective on morality, when we see a moral violation, we decide rationally whether this is morally right or wrong. However, as Haidt demonstrates in his moral dumbfounding studies, when people are exposed to a set of moral scenarios that do not involve harm but include a moral violation, such as incest, they automatically judge that it is morally wrong, but use their rational

processes only to justify the initial moral judgment. For example, Julia and Mark are often used in moral dumbfounding studies:

Julie and Mark are brother and sister. They are traveling together in France on summer vacation from college. One night they are staying alone in a cabin near the beach. They decide that it would be interesting and fun if they tried making love. At the very least, it would be a new experience for each of them. Julie was already taking birth control pills, but Mark uses a condom too, just to be safe. They both enjoy making love, but they decide never to do it again. They keep that night as a special secret, which makes them feel even closer to each other. What do you think about that? Was it ok for them to make love?

When most people read this scenario, they make an automatic (intuitive) response and state that this behavior is morally wrong. However, when asked why, they try to legitimize their judgment in a post-hoc manner. Haidt argues that we are not interested in the truth when making moral judgments like scientists. Rather, we justify our behavior as a lawyer. This approach is called the social intuitionist approach.

In the second part of the book, the moral foundations theory (Haidt 2012) is introduced and it is claimed that morality consists of at least five different dimensions. In Kohlberg's theory, the moral principles that are at the "highest levels" are not to harm and to be fair. Kohlberg's perspective has dominated moral psychology. However, inspired by the anthropological work of Shweder et al. (1997), Haidt (2007) mentions that, apart from these two dimensions, there are at least three other moral dimensions, which he calls loyalty, authority, and sanctity. It is argued that these five dimensions are evolutionary adaptations. While harm and justice constitute the individualizing foundations, loyalty, authority, and sanctity constitute the binding foundations.

In the last chapter, Haidt argues that groups, in general, and religious groups, in particular, come together based on a number of shared moral principles, and crucially, that the differences in moral foundations drive intergroup (i.e., political) disagreement. As morality ties groups together, it also blinds them to the fact that members of other groups can also be good people. Instead,

people view the world from the perspective of their own group.

In general, Haidt's approach suggests that in order to eliminate the conflict between political groups, liberals should appreciate loyalty, authority, and sanctity more than they are generally inclined to. However, an opposing approach (Sauer 2015) argues that since both sides already value individualizing foundations, conservatives should question their emphasis on binding foundations. Although there are a number of empirical studies on what the core moral foundations of humans are (Alper and Yilmaz 2019; Napier and Luguri 2013; Wright and Baril 2011; Yilmaz and Saribay 2017), the current evidence is inconclusive and further empirical studies are needed.

Joseph Henrich

Adam Tratner
Oakland University, Rochester, MI, USA

Definition

Joseph Henrich is an American evolutionary social scientist whose work is primarily concerned with human psychology, decision-making, and culture. Originally hailing from Philadelphia, Pennsylvania, he obtained bachelor degrees in anthropology and aerospace engineering from the University of Notre Dame, followed by master's and doctorate degrees in anthropology from the University of California in Los Angeles. Throughout his academic career, he has incorporated a diverse range of methodologies into his research, integrating ethnographic tools from anthropology with experimental techniques drawn from psychology and economics (Henrich et al. 2004). Using this multidisciplinary approach, he has spent a substantive amount of time studying indigenous peoples in Amazonia, Chile, and Fiji, as well as individuals living in modern industrialized societies across the globe. Henrich applies principles of evolutionary theory to the study of human culture and has investigated a variety of topics both in the laboratory and in the field, including cultural evolution, human sociality, large-scale cooperation, and the social processes that give rise to complex human institutions.

Introduction

Joseph Henrich argues that culture has driven human evolution to the point of complexity that we see today (Henrich 2016). That is, the reason

why humans have been so successful as a species is because we have the ability to create and acquire culture, which provides us with invaluable information on how to survive in a given environment. In only a few million years, our species has emerged from a lineage of primate ancestors to become one of the most successful species on planet Earth. Particularly, within the last 12,000 years following the end of the last ice age, human societies have expanded from relatively small groups of hunter-gatherers into vast nation states with complex social structures and hierarchies. Although genetic evolution laid the foundation for the cognitive processes necessary for the emergence of culture, our subsequent success as a species, Henrich (2016) argues, has been made possible by culture. Culture may also steer genetic evolution by altering the selective environment faced by genes.

Much of Henrich's work investigates how culture shapes our psychology and the structure of the very societies that we live in. Using evolutionary theory, Henrich explores how people both learn and transmit culture. The application of evolutionary principles to studying culture allows for a theory of *cultural evolution* – a way of understanding the mechanisms that drive human innovation and the cumulative cultural processes that shape human societies. The theory of cultural evolution considers the variation in human psychology across the globe, assessing how different environmental inputs interact with our evolved psychology to produce a diverse range of stable cultural systems comprised of adaptive cultural practices. Using this theoretical framework, Henrich has examined phenomena such as social status and prestige in human societies, and their implications for cultural transmission. He has also explored how small-scale cultural transmission provides the building blocks for large-scale cooperation and the emergence of widespread cultural institutions, such as organized religion and political movements.

Cultural Evolution

Similarly, but not analogously to genetic evolution, culture evolves (Chudek et al. 2015; Henrich

and Boyd 2002; Henrich et al. 2008). Culture, like genes, can meet the three criteria of evolutionary adaptation: (1) information varies, (2) variability is heritable and information is transmissible, and (3) some variants are more likely to survive and propagate than others. However, unlike genes, culture can spread *horizontally* across individuals rather than solely *vertically* (as is the case with parent to offspring genetic inheritance; Chudek et al. 2015; Henrich et al. 2008). Furthermore, according to Henrich and colleagues, cultural transmission differs from genetic transmission in subtle, yet important ways – for example, it neither requires replicators (i.e., as compared to discrete, gene replicators) nor random variation for cumulative, adaptive cultural evolution to occur (Henrich and Boyd 2002; Henrich et al. 2008). That is not to say that natural selection does not play a role in cultural evolution; cultural evolution simply attempts to take into account the interaction of psychological processes and the environment in which cultural systems inhabit. For example, some cultural systems may be more useful in one environment, whereas others more useful in different environments.

Henrich asserts that simply understanding how evolved psychological mechanisms and cognitive structures (due to natural selection) can give rise to culture is insufficient in predicting how cultural representations can spread between individuals, be modified, and diffuse across societies (Henrich et al. 2008). To comprehend the bigger picture of how culture develops and spreads, it is necessary to construct formal cultural evolutionary models. Using the cognitive and evolutionary foundations of human social learning, Henrich has created formal, mathematical models of cultural evolution, and such mathematical models reveal how individual cognitive processes can give rise to complex social phenomena through social interaction between individuals. With simple psychological assumptions and decision rules, such models illustrate how a wide range of phenomena, such as the evolution of economic specialization and the emergence of large-scale cooperation (Henrich and Boyd 2001), technological advancement (Henrich 2004), and the spread of innovations (Henrich 2001), can occur systematically. By consulting these models, Henrich has

also developed theories about the emergence of higher-level social phenomena, such as complex institutions (e.g., governments, organized religion), large-scale social groups (e.g., ethnic groups), and social hierarchies (Atran and Henrich 2010; Chudek et al. 2015; Henrich 2009; Henrich and Boyd 1998; Henrich and Gil-White 2001; Shariff et al. 2011).

The products of cultural evolution profoundly influence human behaviors as well as the ecology of human civilization. Interconnected sets of skills, beliefs, values, and institutions have been assembled by cultural evolutionary forces and are defining characteristics of human societies. Culture affects people's motivations, goals, and reasoning processes by compiling the very belief systems and skills that individuals rely on for survival and group living.

Culture-Gene Coevolution

Joseph Henrich contends that there are elements of human social behavior that cannot be understood without considering the joint interaction between culture and genes. Because humans have relied on cultural learning in order to survive for hundreds of thousands of years, culture may have influenced our species' genetic evolution. The cognitive and behavioral capacities that make human culture possible – complex communication skills, social learning mechanisms, and domain-specific information processing systems – evolved because these capacities allow individuals to readily adapt their behavior to novel and changing environments at rates much faster than genetic evolution (Henrich and Boyd 1998; Henrich and Gil-White 2001). Similarly to genetic evolution, cultural evolution is a cumulative process, where human innovation is transmitted and aggregated by individuals. Because of the transmissibility of culture and its utility in aiding our species' survival, culture has shaped human genetic evolution, including our physiology, anatomy, and psychology (Chudek et al. 2015; Henrich et al. 2008). For example, the structure and function of human teeth, changes in digestive processes, our lack of body hair, and acquisition of manual dexterity cannot be understood without

considering that our genes responded to the cultural transmission of cooking with fire, wearing clothing, and tool use. Similarly, culture has likely shaped human cognition by changing the selective environment faced by genes. This process is referred to as *culture-gene coevolution*.

Cognition and Culture

To understand how culture is made possible, it is necessary to investigate the underlying cognitive processes that facilitate learning, problem-solving, and social intelligence. For cultural learning to occur, humans rely on cognitive processes that organize and interpret information coming in from the social world (Chudek et al. 2015). Henrich has tested hypotheses about how these cognitive processes function, taking into consideration how natural selection has shaped human cognition to allow individuals to acquire new ideas, beliefs, values, and practices from other individuals. In order to accomplish this, he has constructed formal mathematical models of cultural learning and generated predictions on how cultural information is both transmitted and shaped by the human mind. Using a wide range of methodologies and techniques drawn from different fields of study, Henrich has investigated how individuals learn and transmit information from others, both in the laboratory and among traditional societies.

Henrich has identified two key components of human psychology that are crucial for acquiring culture, as well as the ongoing process of cultural evolution. The first involves understanding how cognition directs social learning toward particular individuals, ideas, and beliefs, and how cognition makes sense of the available social information. By applying evolutionary theory to understand the processes underlying social learning, Henrich predicted that individuals should use model-based cues of skill, success, health, prestige, and self-similarity (e.g., sex and ethnicity) to decide with whom to pay particular attention to for cultural learning (Henrich and McElreath 2007; Henrich and Gil-White 2001). Similarly, individuals should rely on copying the behaviors exhibited by others around them in the absence of high-

quality social information from skilled cultural models (Henrich and Boyd 1998). The second component pertains to the ways that cultural learners avoid exploitation during cultural learning: natural selection leads cultural learners to rely on inferentially potent (i.e., costly) displays when acquiring cultural information that can be cheaply transmitted via verbal or other symbolic communication. Costly displays are actions that would likely only be performed by cultural models that actually subscribe to the cultural information that they have expressed verbally (Henrich 2009).

Prestige

Prestige can be seen as an emergent product of psychological adaptations that evolved to assess the quality of information obtained through cultural transmission (Henrich and Gil-White 2001). Not to be confused with dominance (e.g., status maintained through force and threats), prestige is more closely analogous to freely conferred deference on behalf of cultural learners, who perceive a prestigious individual to be a purveyor of high-quality information. Natural selection favored cultural learners who could evaluate and imitate successful cultural models that demonstrate mastery of skills as well as knowledge relevant to survival and reproduction (i.e., high-quality information). Cultural learners evolved the tendency to ingratiate themselves with successful cultural models in order to gain close proximity to, and prolonged interaction with, these models. This adaptive bias granted cultural models deference on behalf of their adherents, and some models accumulated more prestige than others. Cultural learners could identify which cultural models have been bestowed the most deference from others and decide which models to emulate. As a result, this led to a general preference for cultural models who appear to be “popular” relative to others (Henrich and Gil-White 2001).

This type of cultural transmission is adaptive because it saves cultural learners the costs of individual learning, and natural selection favors efficient social learning capacities. Furthermore, natural selection favors behaviors that direct cultural learners toward greater interaction with

successful cultural models, as well as establishing cooperation with them. Cultural learners therefore evolved the capacity to provide benefits to targeted cultural models in order to gain greater access to and cooperation with such models. In a sense, preferred cultural models can be seen as having prestige with respect to their subordinates (cultural learners). The most skilled and knowledgeable cultural models will end up with larger followings of cultural learners – a direct indicator of the quality of information that a cultural model possesses (Henrich and Gil-White 2001). Thus, natural selection favors cultural learners who select their cultural models on the basis of their associated prestige. Because high-quality information (e.g., expertise, skill, wisdom) attracts groups of cultural learners who show deference to prestigious cultural models, models benefit from such deference and are incentivized to compete with one another for greater prestige (Henrich and Gil-White 2001).

Credibility Displays

Natural selection shaped our cognitive processes in regard to cultural learning, such that certain inferentially potent behavioral displays – or *credibility displays* – represent honest cues of belief, commitment, and group involvement (Henrich 2009). Ancestral humans faced the adaptive challenge of verifying culturally transmitted information from other people in order to avoid being exploited or misled. Humans evolved to look for credibility enhancing displays that indicate an individual's degree of commitment to, or belief in, verbally expressed mental representations. Natural selection favored a reliance on credibility displays in determining how much to commit to, engage in, or believe in a particular representation.

Credibility displays are a costly display or behavior that provides other individuals with a reliable measure of a person's beliefs or degree of commitment to a group, an ideology, set of values, or beliefs (Henrich 2009). Credibility displays are actions that must be both consistent with a model's professed beliefs and are also actions that a person would be unlikely to perform if this person were to believe something different from

what they expressed symbolically. As a result, these behaviors are often “costly” with regard to how much time, energy, resources, or risk of bodily harm are involved. In other words, credibility displays are seemingly detrimental to the individual when taking into account the costs of engaging in them. Although such behaviors appear expensive, harmful, or otherwise wasteful, engaging in costly, credibility-enhancing displays confers an overall benefit to participating individuals by signaling to others one's honest commitment to certain beliefs or to a community, thereby reinforcing one's credibility within a group and providing access to the benefits of cooperation and group living.

Credibility displays promote group cohesion between individuals, as performing such behaviors can encourage collective commitment if many individuals partake. Joseph Henrich argues that there is a connection between credibility displays and levels of commitment to group ideologies, religious beliefs, and shared values that promote solidarity and cooperation within groups, such that a greater number of credibility displays indicate greater levels of commitment (Atran and Henrich 2010; Henrich 2009). Participation in such costly displays is associated with prosocial in-group behavior because credibility displays indicate commitment to beliefs that may benefit the group as a whole. Groups that require these displays are favored by cultural evolution because they represent honest signals of beliefs and group commitment, which in turn promote cooperation and success in intergroup competition. *Cultural group selection* then spreads interconnected combinations of beliefs and practices, where stable combinations of beliefs and practices promote a group's success over others (Henrich 2009).

Religion

According to Joseph Henrich, religion is the result of coevolutionary phenomena. That is, religion emerged from the interaction between genetic evolution of certain psychological properties and cultural evolutionary processes that further shaped human behavior and sociality. In other words, religion is comprised of by-products of

psychological adaptations (Atran and Henrich 2010) working in tandem with adaptive cultural learning processes (Henrich 2009; Henrich and Gil-White 2001). Religions often consist of counterintuitive beliefs in supernatural agents (e.g., gods, spirits), costly commitments, and ritual behaviors (Atran and Henrich 2010; Henrich 2009; Shariff et al. 2011), and these features of religious belief systems are deeply rooted in our evolutionary history.

Culture and genes may have interacted to make certain aspects of religion – such as the belief in *moralizing high gods* – more appealing and believable (Atran and Henrich 2010; Shariff et al. 2011). Beliefs in omniscient, policing supernatural agents, or moralizing high gods are theorized to be partly the by-product of psychological processes that once served the purpose of overcoming recurrent evolutionary obstacles but have been repurposed as the selective environment changed. For example, psychological mechanisms devoted to agency detection were selected for their ability to detect environmental threats (e.g., predators, prey, other humans) but later may have become instrumental in the conceptualization of unseen, supernatural agents that exert their influence on the natural world as well as human affairs (Atran and Henrich 2010). The development of large-scale human societies brought about evolutionarily novel challenges to human group living as large, sedentary populations faced difficulties in coordinating group behaviors, monitoring the actions of group members, preventing free riders from exploiting other group members, and maintaining group cohesion. To accommodate these new developments in human civilization, beliefs in moralizing high gods emerged to reinforce the punishment of noncooperation, defection, and free riding within groups (Shariff et al. 2011). Moralizing high gods became prominent in religious belief systems as cultural evolution proliferated combinations of rituals and beliefs that instilled greater degrees of commitment to gods who demand cooperation between group members, punishment for those who do not follow certain behaviors, and who monitor behavior at all times (Henrich 2009). Therefore, the existence of moralizing high gods in many modern religions is the result of long-

term cultural evolutionary processes and competition between emerging human societies.

Religions require credibility displays on behalf of their adherents (Henrich 2009). These costly displays or behaviors provide other individuals with a reliable measure of a person's degree of commitment to a religious ideology, set of values, or belief system. This can take the form of behaviors that are seemingly detrimental to an individual's fitness, such as ritual scarification, celibacy, fasting, self-imposed poverty, sacrifices, and even martyrdom (Henrich 2009). However, costly behaviors are potent displays that transmit beliefs to other participants and observers, and religions with such requirements will tend to survive and grow because such costly acts invigorate others' commitment and represent honest signs of dedication to the group's belief system. Religions that demand credibility displays facilitate the cultural transmission of devotion to deities, moral guidelines, and the group as a whole.

Belief in moralizing high gods, costly rituals, and acts of devotion will be more likely to proliferate when the most prestigious individuals in a group display them (Henrich and Gil-White 2001; Henrich 2009). In learning which behaviors to imitate and what to believe, group members will attend to the behaviors of prestigious individuals in an attempt to replicate cultural knowledge that may benefit the learner, resulting in the transmission of religious beliefs. Further, religions that encourage costly credibility displays (e.g., avoidance of food, sexual abstinence, body modification) among prestigious individuals will spread because these individuals are influential models of such behaviors. *Cultural group selection* will favor religions that demand costly credibility displays and that have prestigious cultural role models who effectively transmit beliefs as well as practices that facilitate in-group cooperation, promote group solidarity, and increase competitiveness against out-groups.

WEIRD Societies

Although the majority of psychology research is conducted in the western world, the psychological and behavioral patterns observed in Western,

Educated, Industrialized, Rich, and Democratic (WEIRD) societies may not be representative cross-culturally (Henrich et al. 2010). Henrich and colleagues have noted that, although most research is conducted on WEIRD populations, there are significant differences in many psychological characteristics between the western world and small-scale societies. For example, the Müller-Lyer illusion trumps westerners, whereas individuals in traditional societies tend to not fall for the illusion. Differences in fairness and cooperation have been documented, such that westerners tend to give more fair offers in game theory paradigms (e.g., dictator and ultimatum game). When comparing industrialized civilizations and small-scale societies, there are notable differences in everything from scores on visual perception tasks, fairness and cooperation in economic decision-making, spatial cognition, and even the perception of color. This has led Henrich to conclude that, for behavioral researchers to make generalizable claims with respect to human psychology, a more concerted effort must be made to collect data from societies around the world (Henrich et al. 2010).

According to Henrich, the same principle applies when attempting to draw conclusions from comparisons between industrialized societies, western societies, and even within American samples (Henrich et al. 2010). As for the differences between western and non-western societies, preference for choice, the motivation to conform, prevalence of analytical versus holistic reasoning, attribution errors, moral reasoning, and self-serving biases contrast with one another significantly. Among westerners, Americans (for whom the majority of psychology research is conducted) and other westerners share notable differences. For instance, Americans are consistently the most individualistic and most patriotic and are among those who work the longest hours and are the most productive. Further, Americans significantly differ from other western societies such that they have the highest divorce rate, highest poverty rate of poverty, highest income inequality, and commit more crimes. Even among American research samples, subjects tend to not be representative of other Americans, usually consisting

of college educated, psychology majors, who tend to be children of highly educated and high socioeconomic status families. These individuals are also often more individualistic, less conformist, and less prejudiced than the general population. In sum, there are considerable differences in psychological characteristics and behaviors between large, industrialized societies, western societies, and even the population of North America, signifying that findings in most studies using WEIRD samples may not be generalizable cross-culturally (Henrich et al. 2010).

Taken together, these findings outlined by Henrich and colleagues suggest that the majority of behavioral science research may be drawing far-reaching conclusions from a rather small, atypical subset of the world's population. Researchers often mistakenly assume that their findings are universal, when in fact their findings may, by and large, only be generalizable to undergraduate research participants found in WEIRD societies. Because of the considerable population variation commonly found in behavioral science research, WEIRD subjects may be an inappropriate population from which to make generalizations due to their unique characteristics. As such, research topics may also be limited by the heavy reliance on WEIRD populations. Henrich contends that understanding human diversity is crucial for not only understanding the breadth and scope of psychological phenomena but also for constructing evolutionary theories of human behavior.

Conclusion

Joseph Henrich has made significant contributions to evolutionary science by applying evolutionary principles to the study of human culture. His work demonstrates not only how our minds shape culture but also how culture shapes our minds. In investigating the ways that humans acquire and transmit culture, he has helped pave the way for an understanding of the psychological underpinnings of culture, as well as the ways that cultural processes lay the foundations for complex sociological phenomena. Such insights shed light

on the interplay between cultural and genetic evolution on the development of human civilizations.

Definition

An interconnected set of rituals, beliefs, and norms that emerged due to competition among societies and institutions, often consisting of counterintuitive representations of supernatural agents and culturally acquired beliefs, rooted in the commitment-inducing power of devotions and rituals.

Introduction

Religion is a coevolutionary phenomenon. That is, religion arose from the interaction between genetic evolution of psychological characteristics and cultural evolutionary processes. Religion is

comprised of byproducts of psychological adaptations (Atran and Henrich 2010) and is also a product of adaptive cultural learning processes (Henrich and McElreath 2007). Although modern religions are rooted in our evolutionary history, they are not solely the consequence of genetic evolution, but rather the belief systems themselves are the result of dynamic cultural systems working in concert with natural selection. Indeed, religion can be adaptive by imposing beliefs and practices (e.g., dietary rules, hygiene, eating rituals) that can shape human habits in adaptive ways. However, religion itself is not an adaptation per se; it is a converging set of cultural products, rooted in features of our evolved psychology. The converging components of religion consist of counterintuitive beliefs in supernatural agents (i.e., moralizing high gods), commitment (credibility-enhancing displays, costly displays), and ritual (Atran and Henrich 2010; Henrich 2009; Shariff et al. 2011).

Moralizing High Gods

Beliefs in omniscient, policing supernatural agents, or *moralizing high gods* (e.g., god of the Abrahamic religions), are the byproduct of psychological processes that emerged to serve non-religious functions (e.g., agency detection), combined with cultural evolutionary processes that favored cooperation-enhancing beliefs (Atran and Henrich 2010). With the development of large-scale human societies, evolutionarily novel challenges emerged as large, sedentary populations faced difficulties in coordinating group behaviors, monitoring the actions of group members, preventing free riders from exploiting other group members, and maintaining group cohesion. For civilization to accommodate these new developments in group living, it was necessary to invent and enforce beliefs in “moralizing high gods” that punished noncooperation, defectors, and free riders within groups (Shariff et al. 2011). The central features of religions, such as moral guidelines, traditions, and the belief in one particular god or a specific pantheon of gods, have proliferated due to competition between different cultural groups, with the more

successful groups spreading their respective religious beliefs and practices.

The preponderance of moralizing high gods across world religions is the result of long-term cultural evolutionary processes driven by competition among cultural groups. Moralizing high gods became prominent in religious belief systems as cultural evolution favored combinations of rituals and beliefs that instilled greater degrees of commitment to gods who demand within-group cooperation, punishment of those who do not follow certain behaviors, and who have the power to monitor behavior at all times (Henrich 2009). Beliefs in such gods helped expand human cooperation; the fear of moralizing supernatural agents helped overcome the constraints imposed by the growth in the size of human social groups and the subsequent difficulty in coordinating behaviors and maintaining group solidarity. Thus, the emergence of religions with beliefs in moralizing high gods has been a cumulative process built by our evolved psychology and shaped by changes in the size and scale of competing human societies.

Credibility-Enhancing Displays

According to Henrich’s view, religions will culturally evolve to possess beliefs in counterintuitive supernatural agents, such as moralizing high gods, which demand *credibility-enhancing displays* (CREDs; Henrich 2009). CREs are costly displays or behaviors that provide other individuals in a group with a reliable measure of a person’s beliefs or degree of commitment to an ideology, set of values, or beliefs. For example, practicing celibacy, fasting, eschewing material wealth, performing sacrifices, and even martyrdom can act as CREs of deep commitment to a belief system (Henrich 2009). Sacrifices (including self-sacrifice) are potent CREs that transmit beliefs to both participants and observers, and religions with such rituals will tend to survive and grow because these costly acts invigorate commitment to a set of beliefs. Religions that demand CREs allow for the transmission of deep commitments to the supernatural agents and gods that are found in a given belief system and further spread the belief in the agent(s) (Henrich 2009).

Counterintuitive beliefs, such as supernatural agents and moralizing high gods, will be more likely to proliferate when the most prestigious individuals in a group express CREDs (Henrich 2009). In learning how to behave and what to believe, group members will attend to the behaviors of prestigious individuals and the CREDs that they are performing. Cues of prestige influence people to pay attention to specific individuals for learning cultural information, and prestigious individuals performing CREDs convince group members that they are truly committed to their professed beliefs. Religions that encourage CREDs (e.g., avoidance of food, sex, and wealth) among high-status individuals will tend to proliferate because they have made their leaders to be powerful models of such commitment. Therefore, successful cultural practices involving deep commitment to counterintuitive beliefs will tend to involve prestigious individuals performing CREDs. Cultural group selection will favor religions with role models who effectively transmit beliefs and practices that strengthen in-group cooperation, promote group solidarity, and increase competitiveness against out-groups.

Conclusion

Religion is the result of long-term cultural evolutionary forces that helped shape the complex, large-scale institutions that now dominate the modern world. Religion serves to coordinate human affairs in large, genetically unrelated groups by encouraging cooperation between individuals within groups and enforces these belief systems by invoking supernatural agents. Omniscient, moralizing supernatural agents (e.g., high gods) reinforce interconnected series of religious beliefs that were culturally selected based on their ability to facilitate cooperation in larger groups, promote within-group cohesion, and foster competition with other social groups. Religious beliefs are more likely to proliferate when promoted by prestigious individuals, and CREDs function as honest signals of commitment to belief systems while encouraging the transmission of specific religious beliefs.

Judgment and Decision-Making

Sandeep Mishra¹, Dallas Novakowski² and Josh Gonzales²

¹Faculty of Business Administration, University of Regina, Regina, SK, Canada

²Department of Psychology, University of Regina, Regina, SK, Canada

Evaluations or estimates (*judgments*) inform the intention to pursue a course of action among alternatives (*decision-making*). All of the behavioral

sciences – economics, biology, and psychology – have made judgment and decision-making (JDM) a focus of substantial research. However, JDM has been variously characterized in multiple disciplines and has lacked overarching theoretical integration (Mishra 2014). Evolutionary theory offers such a point of overarching integration. Because all organisms are necessarily products of natural selection, all behavior must be (at least in part) a manifestation of evolutionary pressures (whether positive, negative, or neutral).

In the following, we first summarize theoretical work suggesting that JDM research requires an overarching normative approach (guided by evolutionary theory) and further requires explication of universal currency of decision-making (proxies of biological fitness). Second, we outline that JDM mechanisms must be calibrated around ecological rationality: Decision mechanisms should be fast, frugal, and sensitive to historical and recurrent environmental pressures. Third, we provide examples of how an evolutionary approach can shed light on key topics in the JDM field.

Evolutionary Theory and the Currency of JDM

Normative theories are concerned with quantifying what organisms *ought* to do in a particular situation. In contrast, descriptive theories involve a bottom-up approach based on empirical observations of actual behavior. Descriptive theories are typically constructed from apparent violations of normative theories and are concerned with describing *what* organisms actually do. In evolutionary parlance, normative theories are concerned with functional explanations for behavior, whereas descriptive theories are concerned with proximate explanations for behavior (Scott-Phillips et al. 2011). Both normative and descriptive theories are integral to understanding JDM processes and outcomes given that quantifying both function and mechanism are essential to fully understanding the etiology of any behavior.

The first (and arguably most influential) normative theory of decision-making is *expected*

utility theory (EUT), which was developed in the field of economics (Friedman and Savage 1952). EUT posits that decision-makers seek to maximize *utility*, which is a measure of happiness, gratification, or satisfaction derived from a behavior. Although EUT has been, and continues to be, extremely influential, the currency of utility is vague and has typically been operationalized only at the proximate level (Mishra 2014). In contrast to normative economic theories of decision-making (e.g., optimal foraging theory, risk-sensitivity theory) do not suffer from the problem of vague quantification of a currency of utility. Rather, biological theories explicitly codify that decisions are made around the currency of fitness (Stephens and Krebs 1986).

Humans and nonhuman animals are products of evolution by natural selection and should therefore have cognition shaped by sensitivity to inclusive fitness (that is, the differential reproductive success of self and kin; Hamilton 1964). In humans, however, the pursuit of fitness is not direct; rather, people make decisions based on *proxies of fitness*, which are outcomes that are (or have been) historically statistically associated with reproductive success (Mishra 2014; Mishra et al. 2017). Positive proxies of fitness include access to material resources, mates, status, and positive reputations, among others. JDM should therefore reflect sensitivity to proxies of fitness. Quantification of proxies of fitness as the central currency in decision-making has two key virtues. First, such a currency is not as vague as utility. It can be explicitly quantified, measured, and empirically examined. Second, this currency is derived directly from evolutionary theory, and therefore grounds any understanding of JDM in a broader overarching explanatory framework.

Ecological Rationality and Mechanisms of Decision-Making

Normative approaches to JDM have focused on understanding “rational” or “optimal” decision-making (i.e., seeking to maximize or optimize a particular currency). Key pushback against the

idea of “optimal” decision-making in economics came in the form of the descriptive “heuristics-and-biases” program of research, which quantified the various ways that actual human decision-making countered the predictions of EUT.

Proponents of the heuristics-and-biases program argue that human reasoning is prone to systematic errors (*biases*; Tversky and Kahneman 1974). However, this tradition treats biases as failures of a flawed mind. By contrast, evolutionary theory suggests that while biases may appear to be “irrational” at first glance, they may actually be part of a cognitive system designed to maximize proxies of fitness (reviewed in Haselton et al. 2009). Given the fundamental constraints of cognitive processing – it takes time, energy, and effort to collect information, and almost every real-world decision is made under some constraint of uncertainty or incomplete information – it is necessarily the case that JDM mechanisms must be “bounded.” Most decision-making is characterized by satisficing, which involves seeking outcomes that are “good enough” to meet one’s needs (versus optimal; Simon 1956).

Fast-and-frugal heuristics are simple satisficing cognitive “rules of thumb” that can be simply applied to a wide range of situations. Such heuristics are time, knowledge, and computationally efficient (Gigerenzer and Gaissmaier 2011). However, to be effective, fast-and-frugal heuristics must be well-fitted to the environment of decision-making. In this sense, fast-and-frugal decision-making reflects *ecological rationality*, which describes robust fit between cognitive decision mechanisms calibrated to recurrent structures of regularly encountered environments (Todd and Gigerenzer 2012). The use of heuristics may not always be “rational” in the context of modern environments. However, some heuristics can be considered adaptively rational in that they reflect fit to recurrent past (rather than present) ecologies.

Evolution-minded theorists have posited that human bias occurs for three reasons (see *Bias* entry). First, fast-and-frugal heuristics can be prone to breakdowns in reasoning in systematic ways. Second, humans may have become prone to bias because they developed a preference for errors that impose lower fitness costs. Third,

some instances of bias may be an artifact of environments incompatible with the evolved mind (reviewed in Haselton et al. 2009). Together, this theorizing and research suggests that people make satisficing decisions in accordance with an account of bounded rationality, and that people’s JDM mechanisms reflect ecological and adaptive rationality.

Applying Evolutionary Theory to JDM Problems

An evolutionary perspective suggests that JDM is centered around maximizing proxies of fitness, and JDM mechanisms must reflect bounded and ecological rationality. In the following, we provide examples of how an evolutionary approach can shed light on several commonly studied topics in JDM.

Judgments and cognitive biases. Canonical mainstream understanding of cognitive biases is that they represent systematic errors as a consequence of deviation from “rational” normative judgments. However, many of these supposedly “irrational” biases reflect evolutionary architecture. For example, the *primacy effect* and *recency effect* describe people’s tendency to overweight initial and recent events (respectively) in memory. The *availability heuristic* describes the tendency to overweight salient events in memory. *Attentional bias* describes people’s tendency to differentially attend to recurrent thoughts. The *base rate fallacy* describes people’s tendency to ignore base rates and focus on salient anecdotes.

The list of cognitive biases that have been identified is very large. However, a common thread emerges: most biases involve overweighting salient events in memory, independent of how statistically likely they are. Such biases are obviously ecologically rational: particularly hazardous, dangerous, or important events *should* be overweighted so as to prevent negative fitness outcomes. Ecologically rational judgment mechanisms (especially regarding risk assessment) should overweight salient threats in order to motivate appropriate behavior. In this sense, cognitive biases reflect deep evolutionary logic (an

argument made persuasively elsewhere; e.g., Haselton et al. [in press](#)).

Risk and uncertainty. Risk and uncertainty are inherent properties of essentially every decision. Risk is most widely defined as payoff or outcome variance (reviewed in Mishra [2014](#); Mishra et al. [2017](#)). Uncertainty occurs when decisions involve unknown outcomes (by contrast, risk canonically involves choice only among known outcomes; Volz and Gigerenzer [2012](#)). There are few “real-world” (i.e., nonlaboratory) decisions that do not involve uncertainty. It has thus been argued that uncertainty can be considered a form of immeasurable risk, and that decision mechanisms must be sensitive to (and potentially integrate) risk and uncertainty (Volz and Gigerenzer [2012](#)).

How do people make decisions around risk (and uncertainty?). The recently proposed *relative state model* suggests that there are two pathways to risk-taking: need-based and ability-based (Mishra et al. [2017](#)). Need-based risk-taking is a product of competitive disadvantage, consistent with risk-sensitivity theory (which posits that decision-makers seek risk when unable to meet their needs with low variance options). Those who are competitively disadvantaged (i.e., far from a desired goal) thus upregulate risk-taking. This pathway is inclusive of such widely documented empirical phenomena as the young male syndrome (Wilson and Daly [1985](#)), which describes increased risk propensity among young males who are competitive. By contrast, ability-based risk-taking is a product of an assessment of competitive advantage, where people engage in risk-taking when they possess abilities or traits that increase the expected value of risk-taking and/or have signaling value (e.g., Sell et al. [2009](#)). The relative state model provides an evolutionary account of why both competitively advantaged and disadvantaged individuals engage in (differential) patterns of risk-taking, offering clarification of longstanding arguments about domain-specificity and generality of risk-taking.

Framing and loss aversion. One of the most renowned findings in the JDM literature is that decision-makers are risk-prone when facing losses and risk-averse when facing gains (summarized in highly influential *prospect theory*;

Kahneman and Tversky [1979](#)). Evolutionary theory offers a normative explanation for these findings. Experiencing a loss may bring an organism to the threshold of not being able to reproduce or survive (Hurly [2003](#)). As a consequence, organisms should elevate risk in the face of losses because risk-taking might represent the only way to potentially avoid such dire biological outcomes (consistent with risk-sensitivity theory; McDermott et al. [2008](#)).

Temporal discounting. Human and nonhuman animals engage in temporal discounting: the active preference of smaller, immediate rewards over larger, distal rewards. A large literature suggests that the degree of temporal discounting is dependent on an individual’s perceived time horizon. Those who perceive themselves to have short time horizons (e.g., shorter life expectancy) are substantially more likely to engage in temporal discounting (Daly and Wilson [2005](#)). Such behavior is often interpreted as irrational (why choose outcomes with lower expected values?). However, viewed through an evolutionary lens temporal discounting makes adaptive sense. Individuals who do not anticipate that tomorrow is guaranteed choose options that are available today, especially when making decisions about behaviors related to proxies of fitness (e.g., Krupp [2012](#)).

Perceived time horizons are associated with individual differences in life history orientation, which range from “fast” (comprising a constellation of impulsive, present-oriented behaviors) to “slow” (comprising a constellation of patient, future-oriented behaviors). Substantial research has shown that individuals who exhibit “fast” life histories typically have experienced developmental and/or environmental conditions that cue short time horizons (e.g., high extrinsic mortality, low life expectancy, parental absence, abuse; reviewed in Mishra and Lalumière [2008](#)).

The four broad areas summarized above represent some of the core areas of research and knowledge in JDM. An evolutionary framework offers an integrative, normative understanding of behaviors in all of these areas in that it (a) grounds currencies of decision-making in concrete and quantifiable proxies of fitness, (b) offers an ecologically rational account of decision-making

mechanisms, and (c) has broad explanatory power and scope.

Definition

Judith Jarvis Thomson is a researcher and philosopher who works mainly in the fields of moral theory and metaphysics. She is also well known for her role in the development of variations of the *Trolley Problem* and for her controversial 1971 essay *A Defense of Abortion*.

Introduction

Judith Jarvis Thomson was born in New York City on October 4, 1929. She received her B.A. in Philosophy from Barnard College in 1950, another B.A. in Philosophy from Cambridge University in 1952, a M.A. in Philosophy from Cambridge in 1956, and, finally, a Ph.D. in Philosophy from Columbia in 1959 (Gendler 2009; MIT Philosophy Department 2016). She began teaching at Barnard College in 1962 and married British philosopher James Thomson (they later divorced in 1980). Next, Jarvis Thomson spent a year teaching at Boston University before being appointed to the faculty at MIT in 1964 (Gendler 2009). She has held visiting professorships at the University of Pittsburgh (1976), Yale Law School (1982, 1984, 1985), and the University of California at Berkeley Law School (1983). Moreover, she has held academic fellowships from the Fulbright Foundation (1950–1951), the American Association of University Women (1962–1963), the National Endowment for the Humanities (1978–1979, 1986–1987), the Guggenheim Foundation (1986–1987), and the Center for Advanced Study (Oslo, Norway, 1996) (Gendler 2009). She was also elected to the American Academy of Arts and Sciences in 1989 and served as president of the Eastern Division of the American Philosophical Association from 1992 to 1993 (Gendler 2009). Currently, she still works at MIT as a Laurence S. Rockefeller Professor of Philosophy.

Research

In her 1967 essay *The Problem of Abortion and the Doctrine of the Double Effect*, ethics researcher Philippa Foot discussed the moral distinctions between intended and unintended consequences, and between the duty to do no harm versus the duty to help others, using several examples, including the ethical dilemma now known as *the Trolley Problem* (Grimes 2010). The Trolley Problem outlines an ethical dilemma faced by the driver of a runaway trolley that is speeding toward five workers. The driver must decide whether to divert the trolley onto another track where only

one worker is present, thus sacrificing the life of one person to save five other people. After its initial conception by Foot, Jarvis Thomson created two variations of the Trolley Problem; the first is known as the Loop Variant, which requires a bystander to choose whether to throw a switch to divert the trolley (sacrificing one life to save five, similar to the original dilemma) or not to intervene at all. The second variation is known as the Fat Man Variant, which requires a bystander to choose whether or not to throw an obese man onto the tracks to derail the trolley and save five lives (Cathcart 2013). These two problem variations introduce the options of less action (the Loop Variant) or more direct action (the Fat Man Variant), which can influence moral perspectives and perceptions of blame. Collectively, using the Trolley Problem and its variants to study morality has become known as *trolleyology* (Cathcart 2013).

However, Jarvis Thomson is arguably most famous for her controversial 1971 essay *A Defense of Abortion*. In this essay, Jarvis Thomson argues that, even if contending that the fetus has a right to life, the rights of the fetus do not supersede the rights of the pregnant woman's right to bodily autonomy (i.e., to control her own body) and her body's life-support functions (Thomson 1971). In one example, she defends the permissibility of abortion using the following thought experiment:

You wake up in the morning and find yourself back to back in bed with an unconscious violinist. A famous unconscious violinist. He has been found to have a fatal kidney ailment, and the Society of Music Lovers has canvassed all the available medical records and found that you alone have the right blood type to help. They have therefore kidnapped you, and last night the violinist's circulatory system was plugged into yours, so that your kidneys can be used to extract poisons from his blood as well as your own. [If he is unplugged from you now, he will die, but] in nine months he will have recovered from his ailment, and can safely be unplugged from you. (Thomson 1971, p.48–49)

According to Jarvis Thomson, it is permissible to unplug yourself from the violinist even though your actions will cause his death because of limits on one person's right to life. Specifically, one person's right to life does not supplant the rights

another has to their own body. Thus, unplugging the violinist does not violate his right to life, but, rather, deprives him of the use of your body, to which he has no right (Thomson 1971). Jarvis Thomson extends this argument to the aborted fetus; abortion does not violate the fetus' right to life, but, rather, denies the fetus the nonconsensual use of the pregnant woman's body, to which it is not entitled (Thomson 1971). She therefore concludes that induced abortion is morally permissible.

Conclusion

Judith Jarvis Thomson has authored or coauthored several other notable works, including, for example, *Acts and Other Events* (published in 1977); *Rights, Restitution, and Risk* (published in 1986); *The Realm of Rights* (published in 1990); *Moral Relativism and Moral Objectivity* (published in 1996); and *Goodness and Advice* (published in 2001) (see Gendler 2009). Most recently, she published a book entitled *Normativity* in 2008 and published an article on trolleyology in Frances Kamm's *Trolley Problem Mysteries* in 2015 (MIT Philosophy Department 2016). As of the writing of this entry, Judith Jarvis Thomson was working on a new book on moral theory entitled *Ethics* (MIT Philosophy Department 2016).

Judith Rich Harris

Lies Wesseling
Maastricht University, Maastricht,
The Netherlands

Introduction

Judith Rich Harris is an American psychologist with a scholarly career that has become quite exceptional after a century of professionalized and compartmentalized science. Although blessed with a well-developed faculty for rigorous analytical thinking, two mishaps conspired to sidetrack her from the beaten academic path. First, she was dismissed from Harvard's PhD psychology program in 1960, because she was considered insufficiently capable of original and independent thinking. Second, she was diagnosed with an auto-immune disease in 1977, which confined her to her home and made a career in science even more implausible. Unable to give up on her love for science, she found a way to feed her interest in psychology as an author of textbooks from 1970s up to 1990s. This enabled her to read widely and to familiarize herself with different psychological paradigms, which proved to be of great importance eventually, when she emerged out of the shadows of textbook-authorship with an article in a peer reviewed psychological journal in 1995, followed by the monograph *The Nurture Assumption: Why Children Turn out the Way they Do* in 1998, and yet another monograph in 2006, *No Two Alike: Human Nature and Human Individuality*. Both books engage in detailed criticisms of developmental psychology, while reaching out to evolutionary psychology and

behavioral genetics to develop alternative accounts for the factors that govern the process of human individuation.

Both books address lay audiences. They do not contain any unexplained jargon, and they excel in the art of persuasion through wit, verbal virtuosity, the staging of scientific *personae* (Wesseling 2004) and clever choices of genre. *The Nurture Assumption* combines the expository mode with autobiography (Harris 1998), which enables the author to establish a rapport with the reader. *No Two Alike* has been composed as a whodunit, with the mystery of human individuation posing as the culprit, the author as a private detective (or “academic investigator” as she calls it), who first has to eliminate five false leads before she can identify the culprit, who turns out to be a threesome. One could therefore fit her under the rubric of science popularization, were it not for the fact that this label evokes unwarranted derogatory connotations. Science popularization is often regarded as derivative, as a continual watering down of science proper as information is passed on from one audience to another, producing ever less of the same. Hence, science popularization can only produce cognitive loss; it can never produce new insights. This view of science popularization is wrong, as sociologists and historians of science have argued at length (Whitley 1985; Hillgartner 1990; Nowotny 1992; Lewenstein 1995; Clark and Illman 2001). The argument is that scientists are communicating their theories to diverse audiences all the time, both inside and outside of the academy, and that every act of communication is a translation that may actually produce new insights. The case of Judith Rich Harris substantiates this perspective on science communication. The ability to put different research fields in dialogue with each other without being subject to the “publish or perish” pressure of professional science may help to move beyond entrenched positions and to explore new explanatory models, as we shall see.

Parental Power: A “Cherished Culture Myth”

Harris’s first book, *The Nurture Assumption*, stages a frontal attack on a sacrosanct tenet of

developmental psychology, while taking the child-rearing advice industry that follows in its wake in her stride. Harris argues that psychological research has focused rather narrowly on the formative influence that parents supposedly exert on their offspring, at the expense of other environmental and genetic factors that may also explain “why children turn out the way they do.” The methodological rigor of psychological research leaves much to be desired, as Harris sees it. The confusion of correlation with causation is rampant, and researchers have only been alert to parent-child effects, while ignoring the possibility of child-parent effects, which would make for different relations between causes and effects. Moreover, control groups are often lacking, which makes a longitudinal project such as Judith Wallerstein’s inquiry into the effects of divorce upon 131 children between ages 3 and 18 virtually useless in Harris’s eyes (Wallerstein and Resnikoff 1997; Wallerstein et al. 2000). More specifically, developmentalists hardly ever control for genetic factors according to Harris, which is a further reason why the bulk of their research cannot reveal how the home environment shapes personality in the longer term with any degree of reliability. To top it all off, Harris emphasizes that learning is highly context-specific. Parents may teach their children all sorts of things inside the home, but this does not necessarily carry across to spheres outside the home, which constrains parental influence considerably. Harris therefore concludes that the impact of parents on their children has been grossly overestimated, while evidence to the contrary has been systematically ignored. After half a century of research in developmental psychology, this idea is still just an assumption or “cherished cultural myth” as she calls it, and the author thinks it is about time that we discard it in favor of other, more viable hypotheses.

Genes and Peers

Harris offers two alternative explanations for why children turn out the way they do, namely, one’s genetic make-up and the shaping influence of peers. True enough, intelligent parents tend to

have intelligent children, but this is not because these parents used flashcards or read books to them at length, but because intelligence is largely hereditary. Furthermore, because of the context-specific nature of learning and because we spend only a limited portion of our lives in a family setting, the interaction with peers is bound to exert a stronger influence on the development of our personalities than relationships with parents. Thus, Harris subscribes to the well-established view that both nature and nurture determine how children turn out, but she redefines “nurture” quite drastically, by privileging peers over parents.

Harris’s exposure of methodological flaws in psychological research does not only deal a sensitive blow to academic developmental psychologists but also to science-based child-rearing experts who administer advice to parents through diverse media. If the nurture assumption cannot stand up to critical scrutiny, then it inevitably follows that the dos and don’ts of the child-rearing advice industry are unfounded as well. Harris does not hesitate to drive the message home. Advice-givers likewise exaggerate the impact of parents on children, making impossibly high demands on parents, which degrades parenthood into an anxious, guilt-ridden affair. This does not mean that Harris claims that parents “do not matter,” as many a newspaper article suggested. Clearly, parents have the power to make their children miserable or happy during the time they are together, but they cannot determine their personalities in the long run. As the reception of her book demonstrates, this two-pronged attack gained a wide hearing. *Newsweek*, *New Republic*, and *Commentary* put Harris’s story on their covers. *The Nurture Assumption* was reviewed in leading American newspapers and weeklies, and was a topic on radio and television talk-shows. The British media likewise lavished attention upon Harris’s book (see <http://judithrichharris.info/tna/index.html> for a complete overview of its reception in the press) and it has been translated into some twelve foreign languages (French, German, Italian, Greek, Danish, Finnish, Hebrew, Spanish, Polish, Japanese, Chinese, and Dutch). Determined to get a firmer grip on the “genes and peers” factors, Harris went on to write another book.

The Mystery of Human Individuality

In *No Two alike*, Harris sets herself the daunting task of solving the riddle of human individuality. How come human beings differ from each other to the extent that “no two are alike,” not even identical or conjoined twins? Comparative research into identical twins (genetic similarity is almost 100%), siblings (genetic similarity is around 50%), and adoptive siblings (genetic similarity is zero) enables researchers in behavioral genetics to distinguish between the contributions of genetic and environmental factors to the shaping of human personality. This has led to the insight that genetic factors account for around 45% of human variation. Parenting, Harris repeats once more, accounts for virtually nothing, nor do other factors of the shared home environment appear to have much impact: identical twins, when reared apart, differ just as much (or just as little) as identical twins reared in the same home. Differences within the home environment such as birth order cannot be credited with causing long-term personality differences either, as Harris argues in a lengthy dialogue with Frank Sulloway’s *Born to Rebel* (1996), since systematic comparisons of first-born with later-born children do not reveal consistent patterns of variation across different contexts. Differences between siblings, then, are to be attributed to the “non-shared environment” as the world outside of the home is called in behavioral genetics, which includes the peers that Harris already touched upon in her previous book. However, this nebulous concept may include basically anything and everything, and cannot have much explanatory power as such. Therefore, Harris has made a concerted effort to specify which aspects of the “non-shared environment” could explain why even Ladan and Laleh Bijani, identical conjoined twins who died during the operation that was to separate them, had developed different personalities, while their genes were well-nigh similar, and the one could not go anywhere without the other.

The Modular Mind

Having drawn upon behavioral genetics to account for around 0.45 of human variation,

Harris resorts to evolutionary psychology for the unexplained other half, proceeding from the premise that human variation serves some purpose, that “evolution provided humans with a certain amount of plasticity in behavior so they can profit from their experiences” (Harris 2006, 115). Learning is another word for profiting from one’s experiences, therefore Harris searches for clues in theories of learning, which are necessarily embedded within theories of the human mind. Since humans have lived in groups since time immemorial, it is theories of social learning we need to look for. How is the human mind equipped to fit us to social life? Harris takes her cue from modular theories of mind as elaborated by Jerry Fodor (1983) and Steven Pinker (1997), who claim that cognition is distributed over various functions, and argues that the brain is not a single organ, but rather a conglomerate of mental modules, each taking care of its own specialized function. In other words, modularity of mind implies that there is a specific division of labor between the different modules constituting the human brain. Harris goes on to argue that three specific mental modules are crucial to social learning, namely, the “relationship system,” the “socialization system,” and the “status system,” which she deduces from the different tasks a human being needs to fulfill to function in human society. The first stores information about significant others and helps to establish and maintain consistency in individual relationships; the second gathers information about how we could conform to a specific group that we want to belong to (this is where the “peers” come in); and the third collects information about where we stand vis-à-vis other members of our group, suggesting how we may stand out from or compete with them. The third system is particularly important with a view to explaining non-genetic human variation, for we develop this mental faculty relatively late in life, perfecting it all throughout adolescence and adulthood, whereas the first two develop in early childhood already. This would tally with Harris’s point that the home environment is not of much consequence to the shaping of human individuality. The status system is the faculty that drives us to distinguish ourselves from others and to find our own

little niche in society, in collaboration with the relationship system and socialization system, fitting us to specific divisions of labor that seem to be characteristic of how groups of human beings get things done.

Harris’s Legacy

What is it that Harris has bequeathed to psychology in her late-life, uncredentialed, unpaid, but widely discussed appearances upon the academic scene? Clearly, Harris has engaged in both demolition and construction work. She has not only invested a lot of energy in exposing unwarranted assumptions, flawed research designs, self-serving bias, and immunity to critique in academic psychological research, but she has also attempted to raise new structures after clearing the ground, namely, group socialization theory in *The Nurture Assumption* and the modularity of mind in general and the status system in particular in *No Two Alike*. It has clearly been Harris’s ambition to change the agenda of psychological research, diverting scientific energies away from assessing parental impact on their children in early childhood, to the ways in which human beings adapt themselves to different social environments beyond the home, by offering a theoretical model that could be tested. If we take this ambition very literally, we have to conclude, 12 years after the publication of her last book, that it has not been realized, in the sense that one is hard put to point to researchers that have put her theory to the test. There may be both social and intellectual reasons for this absence of follow-up in a narrow sense. First, it is a mission impossible for a single individual operating outside of the university to set the agenda for groups with vested interests working within this institution. Institutions outnumber and outlast individuals, in science and elsewhere. Moreover, there are also certain self-defeating elements in her bold speculations themselves. If social learning is highly context-specific as Harris emphasizes all throughout, meaning that there is hardly any transfer of lessons learned from one social domain to another, then it cannot be a shaper of personality, understood as a pattern of

traits that remains stable across different contexts and stages in life. The only consistency we would then be left with would be entirely genetic, for genes are impervious to social contexts. Beyond that, we cannot be anything other than shape-shifters if we follow Harris's theory of social learning to its logical conclusion. We would then not only differ from others, but we would also continually differ from ourselves as we move from one social context (e.g., work) to another (e.g., sports), a notion that is hardly conducive to empirical testing.

Having said as much, this does not mean that Harris's publications have remained without consequence in the academic world, as we may infer from specific signs of scientific acknowledgement that are also indicators of impact. First of all, having your work published in peer reviewed journals is a clear sign of scientific recognition, which she managed several times (Harris 1995, 2000a, b, c). To receive an award for a publication is another sign of acknowledgement, and Harris received the George A. Miller Award for her 1995 article, which is named after – irony of ironies – the very scientist who dismissed Harris from Harvard graduate school in 1960. When an authoritative peer-reviewed journal makes room for an extensive commentary by an established scientist and an equally elaborate reply from the author, one can be sure the academic world takes this author seriously (Vandell 2000; Harris 2000b). A similar argument applies to the fact that a leading developmental psychologist, Eleanor Maccoby, took the trouble of producing a 27-page paper in response to Harris's book (Maccoby 2000). *No Two Alike* has also been reviewed by scientists (cf. Ronald 2008, Kaighobady and Shackelford 2000; Anderson 2007) in addition to a wide spectrum of journalists (see <http://judithrichharris.info/n2a/index.html>). On the whole, these scientific reviews are fairly positive, with Shackelford even recommending that Harris's model of the modular mind is put to the test, a recommendation that has not been followed yet, as stated before. Clearly, then, the scientific community has taken due notice of Harris's work, demonstrating that works in science communication may feed back into the

research process, although it is difficult to establish precisely how it has done so.

Given the widespread public acclaim her two books have met up with, Harris's major impact is probably on the public understanding of psychological science. First, her work infringes upon psychology's "biopower," to use a term from Michel Foucault, who argued that the biomedical sciences do not only produce knowledge but also exert power by imposing standards on individuals that distinguish between "normal" and "abnormal" behavior. Psychology certainly also has such disciplinary power. There is probably no other academic discipline which has managed to disseminate its ideas so widely amongst lay audiences and to embed itself so firmly in a wide array of societal institutions as developmental psychology (Rose 1985, 1992). Most citizens of Western welfare states understand themselves and their relationships in the terms of developmental psychology. It has been taken for granted that parents are all-powerful (and that children's agency counts for nothing) for several decades by now, which has sustained the equally widespread notion that parents stand in constant need of expert advice, coaching, monitoring, and intervention, as Foucault's pupil Jacques Donzelot already argued in the 1970s (Donzelot 1977, 1980). After Harris's widely read books, this assumption can no longer be taken for granted, which is sobering for developmental psychologists and the experts who sell their theories to a wider public, but potentially liberating for parents (and their children).

More specifically, Harris's books are bound to have had an effect on the public understanding of the relative merits of evolutionary psychology, behavioral genetics, and developmental psychology. In the shadow which national socialism cast over the twentieth century, it took a long time before behavioral genetics could cast off its detrimental associations with eugenics and racism, a blight that developmental psychology has always been free from, with its emphasis on the environmental plasticity of the child. Harris has certainly done her share in redressing the balance between these fields of inquiry, thereby paving the way towards dialogue and exchange. If she has

deflated the public image of developmental psychology, she has certainly boosted the reputation of evolutionary psychology and behavioral genetics, through her crystal clear expositions of their founding assumptions and basic methods. Thus, even though Harris may not have had a direct impact on the research agenda of developmental psychology, she may very well have had an indirect impact, making it less acceptable for developmental psychologists to ignore the role of heredity in the shaping of human personality.

Third, on the meta-level of knowledge production, Harris's work demonstrates that casting the occasional glance over the walls of one's own area of expertise is a necessary anti-dote against disciplinary bias and career-motivated overinvestment in theories that are sinking under an increasingly heavy burden of anomalous findings. If we grant that professional experimenting scientists are hard put to develop such a broader perspective, given the labor-intensive nature of scientific experimentation, then we should make a greater effort to acknowledge and cherish the vital role of "independent investigators" such as Judith Harris or Oliver Sacks in the overly compartmentalized landscape of contemporary professional science. They are well positioned to identify blind spots and to open the scientific mind to new theories and hypotheses. Conversely, having all your scientific credentials in place, including an affiliation to a prestigious university institute, is not a watertight guarantee for scientific integrity or validity, as Harris has revealed at length, a lesson never to forget. Outsiders within such as Harris or Sacks help to maintain scientific standards, while their curiosity-driven intellectual work embeds scientific research within broader intellectual and scholarly cultures. Through such embedding, specialized scientific research can be made amenable to societal debate, which is necessary, given science's immense impact on the everyday lives of (late-)modern citizens.

Just So Stories

John Alcock

School of Life Sciences, Arizona State University, Tempe, AZ, USA

The just-so story was invented by Rudyard Kipling when writing fanciful tales for small children about such things as how the leopard got its spots (Kipling 1902). The term was then appropriated by others to apply to cases in which a critic thought that an explanation was as juvenile and silly as those provided by Kipling. Although use of the just-so story to denigrate someone else's idea preceded Stephen Jay Gould's use of the term (Smith 2016), Gould's repeated application of the just-so story canard (Olsen and Arroyo-Santos 2015) to sociobiological hypotheses and research (e.g., Gould 1978, 1980, 2002) led to the current tight association between Gould's anti-adaptationist views and the just-so story. While it is true that Gould (with Lewontin) did not use the label in their most famous and widely cited article (Gould and Lewontin 1979), they did criticize the adaptationist program in that paper as one that relies “on plausibility alone as a criterion for the acceptance of speculative tales” (p. 581). In other words, adaptationists (i.e., sociobiologists and evolutionary psychologists) are unscientific types whose enthusiasm for plausible selectionist accounts leads them to accept speculations as true even in the absence of evidence in favor of the idea. The hostile meaning of the just-so story as applied to studies by sociobiologists and evolutionary psychologists was clear to all concerned (Alcock 1988; Holcomb 1996; Kurzban 2002).

However, as Brown (1982) pointed out early on, the “just-so story” label really refers to a hypothesis, a possible explanation, which is an initial step in all scientific investigations. The hypothesis is then used as a prediction generator with follow-on tests of a possible explanation involving checks of the predictions taken from that hypothesis (Sesardic 2003). In other words, Gould would have us believe that producing hypotheses based on natural selection theory was a fatuous activity that led nowhere given the

supposed eagerness of adaptationists to accept speculations on the basis of “plausibility alone.” In reality, silly hypotheses are rare and those that are proposed will be quickly rejected when tested. Since no journal accepts untested hypotheses, testable predictions are universally required by adaptationists. Gould’s use of the just-so story was designed not to improve scientific procedure but to block the scientific study of animal behavior, especially human behavior.

Gould’s examples of just-so stories as applied to species other than humans were limited. He apparently felt that the evolution of the giraffe’s long neck was one such “story,” given that high school textbooks all repeated the standard account of evolutionary change driven by natural selection with a longer neck said to be adaptive in the context of feeding competition (Gould 1996). The widely presented idea was that hereditary variation in neck length enabled the variants with longer necks to acquire food that was out of reach of competitor herbivores. According to Gould, little evidence existed in favor of this hypothesis. And yet if we were to predict that currently giraffes would often feed on leaves of trees growing at heights only giraffes could reach, our prediction would be correct inasmuch as giraffes favor taller trees and preferentially feed on plant material growing 2–4 m above the ground where it is out of reach of the next tallest browsers (Cameron and du Toit 2013; Mahenya et al. 2016a, b).

There is an alternative adaptive explanation based on sexual selection in which long necks are favored in males because of their use as weapons in “necking” combat in which two males competing for access to mates swing their heavy heads and necks into one another (Simmons and Scheepers 1996). Gould (1996) appears to like this hypothesis despite the fact that some researchers have noted that some predictions derived from the sexual selectionist hypothesis might be wrong (e.g., Mitchell et al. 2013). Others feel that the evidence supports both hypotheses or that the data do not invalidate either of the two explanations (e.g., Simmons and Altwegg 2010; Danowitz et al. 2015).

The point here is not that Gould was wrong in failing to anticipate work that would be done after his death. It is that Gould’s just-so story criticism,

applied to an easy target, high school biology textbooks, which was designed to ridicule a hypothesis, has not kept others from using the scientific method to explore the possible adaptive value of long necks in giraffes in terms of feeding competition. And the same is true for another of his just-so story victims (Gould 1978) David Barash, author of a short note in the *American Naturalist* based on a very small sample of experimental observations of the mountain bluebird (Barash 1976). This note, which dealt with the possible adaptive responses of male bluebirds to potential cuckoldry, has been cited 55 times as of 2016, an indicator not of the completeness of Barash’s research but rather of the productivity of trying to test the ideas that selectionist thought generated about adaptation in male behavior in paternal birds, which are not predicted to provide parental care to offspring they may not have sired.

Indeed, as DeBruine (2009) notes, the beauty of evolutionary theory is to alert researchers to hypotheses that they would never have considered were it not for the impetus provided by selectionist thinking. DeBruine supplies several examples of novel predictions about human behavior that were derived from evolutionary hypotheses and then tested, such as the context-specific responses to similar faces (a marker for genetic similarity) that are viewed positively in terms of trustworthiness (relatives are generally to be trusted over nonrelatives) and negatively in terms of sexual attractiveness (relatives are generally to be avoided as sexual partners compared to nonrelatives). As DeBruine points out, without the benefit of evolutionary theory, no one would have thought to propose and then test the idea that the perception of apparent genetic similarity would have two different but adaptive effects on human behavior. Likewise, it was the possibility that selection would increase the probability that paternal male birds would try to avoid being cuckolded by their mates that led Barash to his experiments. The selectionist idea that Barash explored has now been examined by hosts of behavioral ecologists who have produced many papers on the subject. The same is true for the analysis of human behavior by evolutionary psychologists.

The rapid development of the field of evolutionary psychology (Durant and Ellis 2003)

speaks to the failure of Gould's efforts. The only persons who continue to follow Gould's lead in vilifying the adaptationist approach to human behavior are philosophers of science like Buller (2005), Fodor (2007), and Kitcher (1985) and non-scientist commentators like Gottlieb (2012) and Slater (2013). Evolutionary psychologists and other adaptationist researchers have rightly come to ignore the just-so story slur that Gould attempted to apply to entire fields of study.

Kellogg Chimpanzee Study, The

Andrew Franks
Lake Superior State University, Sault Ste. Marie,
MI, USA

Synonyms

[Gua the Chimpanzee](#), [Kellogg study](#), [Winthrop Kellogg](#)

Definition

A study conducted by Winthrop Kellogg to determine the extent to which a chimpanzee can be taught human behaviors and language skills when raised like a human.

Introduction

Comparative psychologist Winthrop Kellogg (1898–1972) was a strong proponent of conducting research to compare the development of humans and nonhuman primates (Kellogg

1931). In the summer of 1931, Kellogg undertook what was intended to be a 5-year study examining the relative influence of heredity and environment on development. The study was conducted as part of Kellogg's Social Science Research Counsel Fellowship at the Yale Anthropoid Station in Florida. The facility (now the Yerkes National Primate Center at Emory University in Georgia) was opened the year before and quickly became one of the main primate research facilities in the United States in part due to Kellogg's work.

Rationale and Goals

Kellogg was inspired by stories of children reared among wild animals in India and popular fiction such as *The Jungle Book* and *Tarzan of the Apes* as well as by the comparative psychological work of Nadezhda Ladygina-Kohts and was interested in examining the relative role of nature and nurture in creating differences in mental abilities (particularly the capacity for complex language skills) between humans and other animals. However, Kellogg knew that it would be unethical to place a child into the wilderness to be raised among animals for an experiment, and so he decided instead to test his nature vs. nurture question by raising a wild animal, specifically a chimpanzee named Gua, as if she were his own child (Benjamin and Bruce 1982). It was important to Kellogg that Gua was “always treated as a human” (Benjamin and Bruce, p. 467), and accordingly she was reared as a sibling

to Kellogg's son Donald, receiving the same diet, toys, and opportunities for learning.

- [Language Development](#)
- [Pinker's \(1994\) The Language Instinct](#)
- [Steven Pinker and Language Development](#)

Study and Findings

At the start of the study, Donald was 10 months old and Gua was slightly less than 8 months old. The development of both "siblings" was carefully recorded, and Kellogg conducted numerous tests to compare Gua's skills to Donald's (Hearst and Capshaw 1988). Gua was able to acquire a number of behaviors traditionally characterized as uniquely human such as utilizing a spoon to feed herself, and she was noted to outperform her "brother" on some behavioral measures (Kellogg and Kellogg 1933). However, Gua did not make any attempt to communicate using human language, while Donald did imitate many of Gua's ape vocalizations (Shusterman 2010). This difference was enough for Kellogg to conclude that innate differences in the brains and bodies of chimpanzees and humans prevented Gua from fully adopting the behaviors expected from a healthy human child (e.g., use of symbolic language), and the experiment was discontinued in the spring of 1932 after less than 1 year (Kellogg and Kellogg 1933).

Conclusion

While the inability of Gua to learn human language was an important factor in Kellogg's conclusions regarding the limits of environmental influences on behavior, teaching language to Gua was not the primary goal of the experiment. The experiment is thoroughly documented in Kellogg's 1933 book *The Ape and the Child*, which was coauthored by his wife Luella. After the study was concluded, Gua was placed in the Yerkes Regional Primate Research Center where she died of pneumonia in December 1933.

Definition

A common factor underlying a cluster of human life history indicators.

Life History Theory

According to life history (LH) theory, individuals allocate resources (such as time or calories) for competing needs. Allocating resources for one need may diminish the resources for the other. This leads to several trade-offs between specific goals. For instance, should an organism invest in current or future reproduction? Should it invest in the quality or quantity of its offspring? Should it exert efforts in mating or parenting? (Del Giudice et al. 2015). The (unconscious) decisions an organism makes regarding these trade-offs comprise LH strategies.

LH strategies tend to generate clusters of traits. These traits include maturation, growth, fertility, parenting, and lifespan. Species differ in their LH strategies. Species that follow *r* (or fast) strategies mature, mate, and reproduce early, producing many offspring (e.g., clams, fish, and frogs). Species that follow *K* (or slow) strategies mature, mate, and reproduce late and produce few offspring (e.g., whales, elephants, and humans).

Individual Variability

Variability in LH strategies exists within species as well. As a group, humans are *K*-strategists since they produce relatively few children and invest substantial resources in each one (as compared with *r*-strategists like fish). However, there is variability among individual human beings regarding the degree to which they exhibit this trait. This variability is a consequence of genetic and environmental conditions.

The traditional approach to measuring both species and individual LH strategy is biodemographic, such as measuring the age of puberty and the number of offspring. Nonetheless, in humans, individual LH strategy can also be measured psychometrically by asking people to disclose their resource allocation preferences. This approach was pioneered by Rushton and continued by Figueredo (see historical review in Figueredo et al. 2013).

Using the psychometric method, Figueredo et al. (2005) collected data from multiple self-

report items related to LH, such as parental and partner attachment, mating effort, and risk-taking. They proposed that there is a common factor – the *K*-factor – that underlies this collection of LH indicators. Using measures of the *K*-factor, people could be divided into high- and low-*K*. High-*K* individuals invest significantly in their family and friends, are long-term planners, and take fewer risks. Low-*K* individuals, on the other hand, invest little in their family and friends, are short-term planners, and take more risks. Figueredo and colleagues showed that the *K*-factor is heritable (Figueredo et al. 2004).

K-Scales

The *K*-factor can be measured using several *K*-scales that have been translated into several languages. The Arizona Life History Battery (ALHB; (Figueredo 2017) comprises 199 items in 7 subscales. Each subscale measures resource allocations of a different domain: (1) insight, planning, and control (e.g., “I try to make sense of the things that have happened to me”); (2) mother/father relationship quality (e.g., “How harsh were they when they punished you?”); (3) family social contact and support (e.g., “During the last twelve months, about how many times have you seen them?”); (4) friends social contact and support (e.g., “During the last twelve months, about how many times have you seen them?”); (5) romantic partner attachment (e.g., “I prefer not to show a partner how I feel deep down”); (6) general altruism (e.g., “I usually vote in local and national elections”); and (7) religiosity (e.g., “I am a very spiritual person”). Most items are rated on a scale of -3 (disagree strongly) to $+3$ (agree strongly). Many of the items were derived from previous scales, whereas others were developed by Figueredo and colleagues. Due to its length, the ALHB is rarely administered.

A more popular *K*-scale is the Mini-*K* (ALHB-SF); this is a short form comprising 20 items (Figueredo et al. 2006). The Mini-*K* is the eighth-AHLB subscale and can be used separately. Its items are not taken from the ALHB; they are generalized statements derived from

the other ALHB items. Each of the seven ALHB subscales is represented by two to three Mini-K items. Sample items are as follows: “I can often tell how things will turn out,” “I avoid taking risks,” and “I have a close and warm relationship with my own children.” The items are rated on a scale of -3 (disagree strongly) to $+3$ (agree strongly). The Mini-K reliability is not high. Both the test-retest reliability and the Cronbach’s alpha are about 0.70 (Olderbak et al. 2014).

Recently, Figueredo et al. (2017) proposed a new short scale – K-SF-42. The new scale incorporates six items from each of the seven ALHB subscales and has better psychometric traits than those of the Mini-K. About half of the items (24) are rated on a scale of -3 (disagree strongly) to $+3$ (agree strongly), for instance, “I am nervous when partners get too close to me.” The other half (18) are rated on a scale of 0 (not at all) to 3 (a lot), for instance, “How much have your friends told you that they liked the way you are?”

The K-factor scales can be placed in a wider context, creating Super-K factors. Super-K factors add general elements to the K-factor. For instance, a Super-K can consist of three components: K-factor, Covitality, and the General Factor of Personality. Covitality includes mental and physical health; the General Factor of Personality is synonymous with the Big-Five personality traits (Olderbak et al. 2014).

Critique

The K-scales have received sharp criticism (Copping et al. 2017; Richardson et al. 2017). The critics claim that the psychometric properties of the K-scales have not been sufficiently studied and, at present, seem inadequate. They question the need to aggregate items from different domains (e.g., parenting, religion, altruism) into one global measure. They also question if the scales measure a single construct and if that construct is correlated with behavioral indicators of LH theory. Last, they claim that some of the subscales (e.g., insight,

planning, and control; mother/father relationship quality) do not measure LH strategy but predictors or mediators of it. They, therefore, consider the K-scales and ones like it as lifestyle – not life history – measures.

Conclusion

The K-Factor is a latent variable underlying a cluster of LH indicators. It aims to measure human individual differences in LH strategy, using a psychometric method. It can be measured using several scales; the Mini-K is the most popular of them. The K-factor and similar psychometric LH scales have been critiqued on psychometric and theoretical grounds.

The reproduction, growth, and survival patterns of killer whales (*Orcinus orca*)

Introduction

The killer whale (*Orcinus orca*), or orca, is the largest species in the dolphin family and is commonly recognized as one of the top predators in our oceans. Killer whales are abundant in high latitude coastal waters; however, they reside in all oceans around the world (Forney and Wade 2006). Because of their wide distribution, they are still considered “data deficient” by the International Union for Conservation of Nature and Natural Resources (IUNC; Reeves et al. 2017). Luckily, several populations of killer whales have been studied extensively for several decades to gain important information on their life history.

Killer whales are considered one species, but there has been some debate whether populations should be classified into subspecies, due to differences in diet, genetics, morphological traits, coloration, and movement patterns (Forney and Wade 2006). Groups of killer whales have been distinguished by socially isolated ecotypes, including those in the northeastern Pacific who are categorized as either *resident*, *transient*, and *offshore*. *Resident* killer whales are characterized by maintenance of stable social networks and feed primarily on a variety of fish species, such as salmon. *Transient* killer whales tend to travel greater distances, have less stable networks, and feed on small marine mammals, like seals and porpoises. Less is known about *offshore* killer whales because of their large geographic range and tendency to be further from coastal waters. They feed on fish, including some species of shark (Baird 2000). Much of the information about killer whales has come from long-term studies of *resident* killer whales around Alaska, British Columbia, and Washington state. Along with these well-studied wild populations, individual whales residing in managed care have also helped us gain a better perspective on how killer whales allocate resources for reproduction, growth, and survival patterns (Robeck et al. 2015).

Reproduction

Killer whales tend to live together in social groups that can range from 2 to 20. Each group is defined by one matriline (descent from the female line) with one to three generations. *Resident* killer whales typically stay with their natal group for much of their life, but offspring of *transient* killer whales sometimes separate from their group when they reach maturity (Baird 2000). There is less information about the behavior of *offshore* killer whales who periodically separate and even abandon natal groups (Robeck et al. 2015). Mating occurs between individuals of different pods, which are composed of many matrilineal groups.

Similar to many other mammalian species, killer whales begin reproducing at an older age and produce few offspring. Male killer whales begin to sexually mature starting around 12.4 years old (Matkin et al. 2014). In the wild, the age of first reproduction for females is also around 12 years. Females born in managed care have been known to reach about 7.5 years of age by their first estrus and around 9.8 years by their first conception (Robeck et al. 2015). Killer whales have long reproductive lives; females stop reproducing around 30 to 40 years old. Like all other whale and dolphin species, killer whales give birth to a single calf. Though it is possible for whales and dolphins to give birth to twins, this is very rare. Thus, females may give birth to several offspring throughout their reproductive life span.

The gestation period for killer whales can range from 15 to 18 months (Duffield et al. 1995), which is longer in comparison to many other species of dolphin (typically around 12 months). Having a long gestation period helps balance the cost of producing large offspring, as calves of toothed whales are typically between 40% and 48% of adult female length (Chivers 2018). Gestation requires low energy investment that is compensated by longer calf dependency.

After birth, calves stay close to their mothers for protection, social bonding, nutritional, and locomotor support. For the mothers, lactation may be the most energetically expensive facet of reproduction, as producing milk with high protein and fat content is crucial for the development and growth of their

calf. Weaning is estimated to occur around 1.5 to 2 years when the calf begins to learn foraging techniques from their relatives (Baird 2000). The intervals between calf births range from 2 to 14 years, but the average is typically between 3 and 7 years. It has been noted that these intervals likely increase over time as mothers age (Matkin et al. 2014). Having a lengthy gap between births allows mothers to provide support for successful growth and survival of their offspring.

Growth

On average, the body length during the first year of life for resident killer whales is 2.7 m (Fearnbach et al. 2011). The rate of growth occurs rapidly from birth and throughout weaning and slows until sexual maturity. One sexually dimorphic trait that is apparent in this species is that males tend to reach a larger body size and have longer appendages compared to females. This is because females typically reach their full body length around 14.5 years, whereas males take longer to mature physically and do not reach their full body size until around 18 years (Fearnbach et al. 2011). Also, males have an additional spike in growth around sexual maturity, indicated by an increase in dorsal fin height. The average body length for southern *resident* killer whales in Alaska is 6.5 to 7.2 m for adult males and 5.5 to 6.4 m for adult females, which seems to be consistent with other populations of killer whales around the world (Fearnbach et al. 2011). One factor that may affect growth in killer whales is food availability. For example, one study found that younger adults were 0.3 m shorter than older adults after experiencing nutritional stress due to a decline in salmon stock (Fearnbach et al. 2011). While transfer of energy from mom to calf and food availability may influence growth rate, it also greatly impacts survival.

Survival

Like many mammalian species, killer whales have higher mortality rates for younger and older

individuals (Matkin et al. 2014). The mortality rate for wild killer whales younger than 6 months is estimated to be around 37% to 50%, though this rate slowly declines with age until 12 years for male and 20 years for females (Olesiuk et al. 2005). Calf survival past the age of two in managed care has improved over time and may be greater than some populations in the wild, including southern *resident* killer whales of the northeastern Pacific (Robeck et al. 2015). For individuals residing in managed care, average life expectancy is 41.6 years. Northern residents are similar with an average life expectancy of 42.3 years, while for southern residents, it is 29.0 years (Robeck et al. 2015). The maximum longevity of killer whales is estimated to be around 80 to 90 years of age for females and 50 to 60 years for males.

Females have a prolonged postreproductive life span, like humans, that is an adaptive benefit for aiding the fitness of their kin. For example, older females improve reproductive success and survival of individuals in their matriline by passing on ecological knowledge by leading group movements, particularly when food is scarce (Brent et al. 2015). These matriarchs are likely to be of value in the current environment where killer whales face many anthropogenic threats, including habitat deterioration and reduction in prey abundance due to pollution and overfishing. Boat traffic is also negatively impacting this species along with many other marine mammals through collisions, noise, and presence that disrupts important activities such as foraging, resting, and socializing. Although killer whales have no natural predators, the negative effects of humans have caused several populations to be endangered, threatened, or vulnerable.

Conclusion

Killer whales have a unique social group network based on matrilineal descent. Populations of killer whales differ, leading researchers to categorize them into ecotypes. Though there is still much to learn about killer whales, research on the *resident* ecotype in the northeastern Pacific and individuals

residing in managed care have been essential for gaining knowledge about life history parameters in this species. Killer whales begin reproducing later in life, which requires more involved parental care. However, this high investment strategy involves the risk of some offspring not surviving to reproductive age or reproducing their maximum potential. Killer whales are one of the only species, other than humans, in which females have a lengthy postreproductive period of life. These individuals are valuable for the success of their kin. Further investigation on killer whale reproduction, growth, and survival patterns can help us understand the impact we have on this species, and from this we can educate the public on sustainable practices to help conserve killer whales, as well as many other marine mammals around the world.

Definition

Kin detection by odor refers to situations in which an organism recognizes a conspecific using organism specific odor cues. Once recognized, behaviors towards that conspecific may be triggered or inhibited resulting in an increase in overall fitness. For example, humans seem able to identify the odors resulting from differences in the major histocompatibility complex (usually unconsciously), thus avoiding in breeding with close genetic relatives and increasing hybrid vigor because of the increased variability in offspring MHCs.

Introduction

Kin selection, proposed by Hamilton (1964a, b), argues that overall fitness can be increased not only through direct transfer of alleles from parents to children, but also indirectly by aiding the survival and reproduction of relatives (kin) who share copies of the same alleles. Kin selection acts in two main ways: by helping relatives directly and by selectively avoiding mating with conspecifics thus avoiding inbreeding depression with its attendant evolutionary consequences.

Hamilton (1964a) argued that the cost of helping kin must be less than the overall benefit moderated by the coefficient of relatedness. In practice, this means that more altruistic help should be given to close relatives compared to distant relatives, and altruistic behavior should be absent with strangers, and even friends, as they do not share family alleles. But this leads to the question, if you can increase your overall fitness through aiding kin, how do you identify kin to aide?

Both proximate and ultimate aspects of kin recognition have been proposed to be important in kin selection (Reeve 1989). Reeve (1989) proposed a theory of conspecific acceptance thresholds, i.e., the criteria which must be satisfied in order to successfully identify kin. The first criterion was argued by Reeve (1989) to be the perception and identification of “kin” signals; secondly there must be processes which confirm the “other” as kin through matching to a stored template and finally there must be mechanisms which inform an appropriate behavioral response.

Methods of Kin Detection

Over the years several methods have been proposed for the identification of kin in humans. These explanations fall into several main theoretical positions, such as phenotypic matching using visual, acoustic or olfactory cues following imprinting at an early age or familiarity (such as being raised together), or self-reference where an awareness of self allows matching to kin. In humans there is additionally active specification, i.e., when parents directly indicate kin, e.g., *this is your cousin*.

Each method of kin selection has advantages and disadvantages, depending on the physical and social environment of the individual. Using sensory cues, such as self-referenced smell to identify kin, can be considered a reliable mechanism as imprinting and familiarity are open to error via adoption and alloparenting of genetically unrelated individuals. Visual and auditory cues may change over an individual's lifetime, while olfactory profiles in contrast have been found to be more developmentally stable (Curran et al. 2005), i.e., they remain constant over the majority of an individual's lifespan, although

changes occur with aging and ill health. Moreover, olfactory cues have been found to reliably co-vary with genetic relatedness, meaning they are an accurate, long-term cue to identify kin. Importantly individuals do seem to be able to reliably identify their own smell (Olsson et al. 2006), meaning self-referent odor similarity is a possible mechanism for kin selection, which eliminates the need for imprinting or early life experience with kin.

Detection of Kin Using Odor

What then is involved in the detection of kin using odor? This is an important question as our awareness of odor does not always reach the level of conscious awareness, suggesting that our behaviors in relation to odor are likely to be unconsciously mediated. A useful starting point is to identify the areas of the body that are particularly odoriferous.

In humans the axillae seem particularly important for odor generation and therefore kin identification, leading Richard Dawkins to coin “the armpit effect” in Dawkins 1976. The axillae may have gained prominence in odor signaling because of human bipedalism and therefore the relative height proximity of the axillae to the sensory organ of olfaction in others. Both eccrine and apocrine glands are important in odor generation, although the latter are likely more important as they are particularly concentrated in the axillae. A genetic factor influencing individual odor is the highly polygenetic (and therefore polymorphic) major histocompatibility complex (MHC). Each individual possesses a unique set of MHC genes, and these act in combination with the body's other processes (such as sweating) to produce a characteristic odor profile (odor-type) which is singularly their own. Thus, Reeves' first criterion has been met. The second requires the identification of processes that confirm the “other” as kin. Olsson et al. (2006) found that smelling a stranger activated the same parts of the limbic system as fearful stimuli, while the odor of a friend activated areas involved in feelings of familiarity. Thus, we can distinguish friend from foe, but can we distinguish kin?

Emma Marxer-Tobler and Jamie Pineda investigated this by testing whether people could

recognize shared ethnicity using body odor alone. They looked at the ability of participants to use body odor to differentiate between themselves, members of their own ethnic group, and members of a different ethnic group. German, Korean Taiwanese, and Chinese students were asked to wear cotton T-shirts over a period of four consecutive nights without use of de-odorants or other artificial scents (participants were also given information on foods to avoid, such as garlic). They were then asked to rate the familiarity of their own T-shirt and T-shirts from their in-group and out-group ethnicities (participants were naïve as to which were which). A total of 75% of participants rated T-shirts from the same ethnic group as familiar, but could not specifically identify from which condition they came. EEG readings were also taken, and it was found that participants' electrode responses to self-odor were most similar to those for in-group odor (Marxer-Tobler and Pineda 2012). The authors concluded that people can discriminate members of their in-group ethnicity using self-referencing odor and that this can be achieved without conscious awareness.

Several studies have shown that odor identification can be even more specific, for example Weisfeld et al. (2003) found that people can identify genetically related family members by scent alone. Participants could use odor to correctly identify a T-shirt worn by their mother 86% of the time, a stranger 91% of the time, their brother, father or sister 59% of the time, and themselves 50% of the time. Interestingly, errors in identification were symmetric, so that, for example, a sister's odor was confused with the mother's and vice versa, and a stranger's odor was symmetric with a friend or spouse's odor. Odors from kin were rarely confused with those from nonkin. So it seems that we can use odor to identify kin with reasonable accuracy.

Differential Behavior Resulting From Kin Identification Using Odor

The final aspect of Reeve's criteria is whether differential behavior results from kin identification. A great deal of research has looked at

behaviors in a mating context, particularly aspects relating to MHC. Repeated studies have shown that in humans, females are more likely to mate with a male who has a MHC smell profile dissimilar to their own and are sexually repulsed by males with a similar one (Wedekind et al. 1995). Mating with conspecifics is therefore avoided, reducing inbreeding depression and ensuring an enhanced immune responsiveness in any resulting offspring.

There is less evidence as to specific altruistic behaviors resulting from kin identification. Dubas et al. (2009) investigated whether parents could identify their children by smell; 79% of mothers and 67.7% of fathers could do this. But more importantly in terms of behavior, fathers who could identify their children by smell engaged in more positive behaviors with them, such as increased levels of attention and play.

Kin Detection Outside the Laboratory

Research in the laboratory has generally supported olfactory kin selection theory and met Reeves three criteria. However, outside of the laboratory life is not so simple. The majority of people nowadays attempt to over-ride their natural odor through the use of de-odorants and perfumes. But how successful are we at disguising our body odor? Allen et al. (2015) investigated this using a three-fold testing method. Individuals providing odor samples were initially matched on their deodorant brand use. Odors were collected through the use of cotton pads over 24 h in three conditions: (1) no deodorant, (2) their usual deodorant, and (3) an assigned deodorant. Participants in the study were presented with three 500 ml odor samples, two of these were from the same individual, and the third was from a different individual. The participant's task was to identify the odd smell out. The results indicated that the proportion of correct responses was highest for the no fragrance condition, compared to the usual deodorant condition, which was higher than the assigned deodorant condition. The authors concluded that fragrance does not mask information contained in body odor, and moreover that deodorants are chosen (probably unconsciously) to complement an individual's own body odor.

In our ancestral environments, humans probably lived in extended kin groups, meaning that individuals rarely came into contact with completely unrelated others. However, this is not the case in the modern world, so that social behaviors which evolved in the Pleistocene may no longer be adaptive in the twenty-first century. In evolutionary terms, helping nonrelatives is maladaptive, as resources are wasted on nonkin alleles (Hamilton 1964a), and olfactory kin selection evidence supports this idea (Selwyn and Meakings 2015). However, in today's world, we now spend proportionately more time with friends than family, due to increased geographical mobility and the frantic pace of twenty-first century living. Evolutionary mechanisms are often plastic, allowing for appropriate responses to a changing environment. Olsson et al. (2006) found that the odor of a friend could induce feelings of familiarity (and therefore potentially altruistic behaviors), particularly when the friendship had lasted for more than three years.

Conclusion

The term 'olfactory kin selection' is misleading to some extent, as it suggests that the identification of kin is the key biological imperative. The term accords the identification of non kin (via their body odor) to a lower status, when actually this ability is equally important in fitness terms. For example, olfactory cues to kin/non kin have relevance both in avoiding inbreeding depression by selecting a mate that is not closely related, and in bonding and caring for your own offspring rather than offspring which are unrelated. Moreover, despite our modern day obsession with concealing our natural odor through the use of perfumes, we can still detect an individual's body odor over and above externally applied scents (Allen et al., 2015). Furthermore, the warm feelings generated by the body odor of friends, reflects the structure of society as it is today, rather than the close knit kin groups of our evolutionary past. Clearly, there is plasticity in the olfactory kin recognition system, allowing it to respond flexibly to changes in social organization. Perhaps in today's complex

and geographically mobile society, friends (as colloquially suggested), really are the new family (at least in olfactory terms).

Definition

Kinship is a “system of social organization based on real or putative family ties,” according to Encyclopædia Britannica.

And when it involves the social fabric which ties families and societies, the sociologists define it as, “Kinship is the most universal and basic of all human relationships and is based on ties of blood, marriage, or adoption” (Crossman 2019, p. 1).

Introduction

Among all social mammals, humans are organized communities of relationships that are focused around everlasting unions between family ties (Koster 2018). When younger siblings co-reside in a family with elder siblings, relationship between them may have significant effect on their growth and developmental, psyche, or behavior (Nitsch et al. 2012). Though social ties through common ancestry are among the oldest forms of sociality where young are nurtured by elder siblings, the psychology of kinship across human societies regularly co-opts sentiments

geared toward genetic relatives and extends them to unrelated strangers also (McNamara and Henrich 2016).

The common phrase, blood is thicker than water, is used to value the importance of family. People, who are related by blood, have stronger cooperation to each other over the people outside their family. Many studies suggest that kin selection with elder and young siblings can have manifold effect on cooperative behaviors in later stage of life, especially in smaller societies (Apicella et al. 2012; Lieberman et al. 2007).

In spite of the evolutionarily ancient roots, facts about the distinctive effects of kin selection on human psychology are mixed. Even, over the time, the phrase also has switched meanings, where it was “the blood of the covenant is thicker than the waters of the womb” (connections made through birth; Jack 2005). This self-contradictory history of the idiom also encases the critical nature of this kinship psychology. As we find that kinship norms establish only one of the several norm systems, we employ to exercise cooperation (Kimbrough and Vostroknutov 2013; Sripada and Stich 2006). And many studies suggest that kin relationship may only manifest a certain amount of human cooperation (Laland et al. 2010; Richerson and Boyd 2006; Richerson et al. 2010). It is also found that in societies with loose kinship, cooperation is promoted through universal moral values; a feeling of guilt; altruistic punishment; and an evident up and down of moralizing religions (Enke 2017).

From our own experience, we find that human being’s tendency toward cooperation may change through the course of stages of life. The present essay addresses effects of kinship interactions on siblings’ cooperativeness.

Context: Kinship and Cooperativeness

During the growing years of life, I have come across many friends and have experienced that the children who have siblings are more considerate and cooperative in nature. I remember that we were a group of elder sisters who would not only take care of our own siblings but also look

after the well-being of our friends and their siblings too. In contrast few of our friends who had no siblings would remain mostly aloof from extending help in time of need. We never even expected cooperation from them.

Antfolk et al. (2014) found that support from parents and similarities in physique and behavior among siblings predict the subjective certainty in relatedness and kin-directed behavior (i.e., cooperative behavior and inbreeding aversion).

Kinship relatedness among siblings is indeed a strong force in cooperation and trust patterns. Kinship mostly the influence of elder sibling on younger promotes social structures and cooperation patterns; similarly psychological, biological, and institutional variables also coevolve through kinship (Enke 2017).

From my own experience, I realized many a times that kinship develops cooperation. During one such experience, Once my elder daughter at the age of 15 accidentally had a dog bite on her nose by a pet dog resulting in profuse bleeding. Incidentally all her friends ran away, but one small unknown child of only 10 years accompanied her to our apartment and stayed with her till he handed over my daughter to me. As I settled with my daughter's condition, I visited the child's home in our premise and understood that he is taken care of by his elder sister along with a keeper, while his mother is at work. The elder sibling relatedness might have induced the cooperative behavior in the child.

Youth mostly cooperate according to their experiences in neighborhood regardless of their previous actions and influence of family values including kinship cooperation (Gutiérrez-Roig et al. 2014).

This is also supported by Greene (2014) who purported that, among youth with tight kinship, societal structure and behaviors evolve through in-group loyalty and cooperation. Kinship promotes cooperativeness even in the absence of parental love and care. Often it is observed that even though a child experiences parental absence due to death or any other reasons, parental love is compensated by the child's other kin to develop the child into a social cooperative being (Winking

et al. 2011). As both of us are working couple and often have work-related trips outside town, we have experienced that our daughters are extremely cooperative to each other and even compensate for our absence from home. They also cooperate with their friends and extend to others in the society as well.

Scientists have found that cooperative breeding from kin has a potentially vital role in the evolution of human prosociality (Hrdy 2009).

It is evidenced that elder siblings can make an advantageous contribution toward younger siblings' social cooperative behavior (Nitsch et al. 2013).

Many observational studies suggest that kin selection helps in increasing cooperation, especially in small-scale societies (Apicella et al. 2012; Lieberman et al. 2007).

Being into the teaching profession for more than 15 years, I have closely observed the students and noted that adjustment, cooperation, and cooperative nature are more among students who have siblings than who are brought up as a single child. This is supported by the work of Henrich (2015) that togetherness and tight kinship systems often contribute to "clannish" social structures and are thereby directly related to the people's cooperativeness toward other members of society.

Context: Kinship, Cooperativeness, and Related Factors

According to cultural anthropologist and social organizations, cooperativeness is largely determined by historical kinship systems (Dousset 2011).

In societies, mankind evolved through kinship system is influenced by culture, different types of rules, and norms that control kin psychology and are used to regulate behavior toward others specifically to all close knit family members. Studies support that cooperativeness among youth is influenced by kinship and aging.

Hulkenberg (2015) in his study shed light on the influence of culture layers of normative kinship build up on the preexisting genetic

relationships to facilitate further more extensive cooperation in the early evolution of increasingly complex social groups.

Despite this relatedness through common genetic ancient roots, humans often co-opt and extend cooperativeness to genetically unrelated others through culturally acquired kinship systems (McNamara and Henrich 2016). They further supported the effect of culture on normative kinship and the preexisting genetic relationships in increasing cooperation during early evolutionary years of complex social groups.

Findings also show the low cooperation found between children with tight kinship and the rest of in-groups but high cooperation by the elderly toward out-groups as they age (Gutiérrez-Roig et al. 2014).

Context: Kinship, Cooperativeness, and Contradiction

Often it is found that kinship norms not only contribute to kin-focused psychological mechanisms more strongly but extend effectiveness to include genetic nonrelatives and sometimes counter activation toward actual genetic relatives even (Henrich 2015). Thus, this set of norms may expand cooperation beyond genes.

Kinship advocates relatedness and coalitions to some extent. In kinship relationship both competition and cooperation are very important issues (Smith 2014).

Not only cooperation mechanisms for youth interactions with genetic relatives matter, human kinship also revolves around extensive cooperation with genetic nonrelatives (Henrich 2015).

Kinship rarely promotes patience in primates and largely fails to protect individuals from hostility. Smith (2014, p. 192) describes that an “individual’s closest friends and follies, many of whom may be kin, are most often an individual’s closest competitors, the siblings within the social groups.”

Although support networks are organized around kinship, covariates that test predictions of kin selection models do not receive strong support, potentially because most kin-directed

altruism occurs within households, not between households (Koster 2018).

Scientists have supported that in societies with tight kinship systems, youth have shown strong in-group favoritism. Youth were found to cooperate less with out-group members in games and even cheated them but have shown highly helping attitude to in-group members (Green 2014).

Contrasts have been drawn where societies with loose ancestral kinship ties have been seen to cooperate effectively and trust broadly (Enke 2017).

Evidence shows that societies with a historically tightly knit kinship structure regulate behavior through communal moral values, revenge taking, emotions of external shame, and notions of purity and disgust (Enke 2018).

Genes from common ancestors are considered the oldest social bonds.

Cooperativeness nature in human beings is influenced by many factors, and from the evidences available, of course kinship mainly, the relation between siblings cannot be attributed as one of the strongest reasons.

Conclusion

The present discussion highlights some aspects of youth cooperativeness and kinship ties especially the influence of elders.

There is a positive relation that exists between kinship tightness and cooperation with in-group members due to underlying trust, however opposite is also found with out group members due to lack of trust (Enke 2017).

It is also evident that the role of genetic kinship among siblings as a fundamental belief principle for constituting cooperative human genre might be less supported in certain cases than previously thought to be (Alvard 2009).

However, several studies purport that kinship norms are one of the many norm systems to facilitate youth cooperation where elders are closely related to young siblings (Kimbrough and Vostroknutov 2013).

In spite of much contradiction, kinship is essentially a helping aspect in bringing up

cooperativeness among human kind. Kinship mostly the sibling relationship boosts cooperation and altruism toward genetic relatives and beyond (Kurzban et al. 2012).

It may be concluded through the writers' own experiences and scientific evidences that kinship encourages cooperative behaviors among youth.

Kin Interest in Mating Relationships

Pieter van den Berg

Lab of Socioecology and Social Evolution, KU
Leuven, Leuven, Belgium

Definition

Human mate choice is often strongly influenced by kin, notably parents. This can lead to conflict over mate choice, because these individuals have different evolutionary interests.

Introduction

In many cultures, parents have a strong (if not complete) influence on the mate choice of their offspring. Arranged marriages are a clear example of this. Research across cultures has shown that parents and their offspring do not agree about the importance of various characteristics in a mate. For example, offspring find it more important that their mate is physically attractive, whereas parents care more that they come from a good family background. This conflict over mate choice may be a product of evolution. The evolutionary interests of parents and their offspring overlap, but they do not entirely coincide. Because they are not equally related to their family members, the survival and reproduction of these individuals are not of equal importance to them. This evolutionary conflict can result in a conflict over mate choice in a number of different ways.

The Evolution of Human Mate Choice

The evolution of mate choice is an interesting but complicated topic. Sexual traits evolve in a complex interplay of selection pressures that the sexes impose on each other. The evolution of sexual preferences in the one sex affects the evolution of sexual characteristics in the other and vice versa. This coevolution can lead to intricate

evolutionary dynamics and surprising evolutionary outcomes. There are many famous examples, from the extravagant tail of the male peacock to the huge antlers of the Irish elk, which were so costly to produce that some believe they drove the species to extinction (Moen et al. 1999). Evolutionary biologists have used various methods to model the evolutionary dynamics that result from sexual selection, from evolutionary simulation models to mathematical methods such as population genetics and invasion analysis (reviewed in Kuijper et al. 2012). These models have helped us understand how evolution may have shaped the sexual characteristics that we observe in nature, including exaggerated sexual traits such as the peacock's tail (Fisher 1930; Zahavi 1975; Andersson 1994; Qvarnström et al. 2006). Empirical biologists have gone out to test the predictions of these models, often inspiring a further refinement of models in return. This close interaction between theoretical modeling and empirical research has been essential for advancing our understanding of the highly intricate topic of sexual selection (Andersson and Simmons 2006; Kokko et al. 2006; Kuijper et al. 2012).

In humans, the complex process of sexual selection is further complicated by another important factor: parental influence on mate choice. Parents in many cultures influence the mate choice of their children, both throughout history (Buunk et al. 2008; Apostolou 2012) and across geography (Minturn et al. 1969; Apostolou 2010; Buunk et al. 2010). In some cultures, such as India, China, Japan, and the Middle East, it is common for parents to arrange the marriages of their children, effectively exerting full control over their mate choice (Hatfield and Rapson 2006; Buunk et al. 2010). Also, in almost all present-day hunter-gatherer societies, there is at least some degree of parental influence on mate choice (Apostolou 2007a). Although parental influence on mate choice is less prevalent in most Western cultures, this is a relatively recent development (Apostolou 2012), and some parental influence on mate choice also remains there, especially among immigrant groups (Buunk et al. 2008).

We should expect the impact of parental influence on mate choice to be negligible if parents and their offspring essentially agree on what are the ideal characteristics for a mate. However, this is generally not the case. It has repeatedly been shown that parents and their offspring place emphasis on different qualities when assessing the value of a potential mate for the offspring. Specifically, parents give more importance to characteristics such as family background and social status, whereas offspring place more emphasis on attributes like physical attractiveness and smell (Buunk et al. 2008; Apostolou 2010, 2015; Perriloux et al. 2011). Similar results have been found across various different sample groups, including people from the Netherlands (Buunk et al. 2008; Dubbs and Buunk 2010), Argentina (Buunk and Castro Solano 2010), and Japan (Dubbs et al. 2013).

Why do parents and their offspring disagree on mate choice? This entry will discuss why evolution may have led to the emergence of this conflict. To do this, we will first examine the evolutionary interests of the involved parties and how they differ from each other. Next, we will discuss how these diverging evolutionary interests can result in a conflict over mate choice. Finally, we will briefly go into conflicts over mate choice that individuals may have with family members other than their parents.

Evolutionary Conflict Between Parents and Their Offspring

Why would parents and offspring disagree about anything? After all, parents and their offspring share many of the same genes, and both have an evolutionary interest in spreading those genes into future generations. However, even though parents and their offspring have overlapping evolutionary interests, these interests are not completely aligned (Trivers 1974). Parents are equally related to each of their children. This means that their evolutionary interests are served equally regardless of which of their offspring spread their genes. It is in their evolutionary interest that the *total* fitness of all their offspring is as high as possible.

Hence, parents are selected to allocate their parental resources according to that objective. This does not necessarily mean that they should allocate their investment exactly equally among all offspring. Under some circumstances, parents maximize the total fitness of their offspring by preferentially investing in young that are in relatively poor condition, whereas in other circumstances, the reverse is true (Davis et al. 1999; Caro et al. 2016). However, all else being equal, parents have no *a priori* reason to give any of their offspring priority when allocating parental resources. From the point of view of the offspring, matters look quite different. Each offspring has a stronger evolutionary interest in their own reproduction than in the reproduction of their siblings (with whom they do share some of their genes, but not all). Therefore, each offspring prefers a skewed distribution of parental resources, favoring investment into themselves over investment into their siblings.

There are many examples that show the consequences of this evolutionary conflict of interests between parents and their offspring. For instance, in families of Galápagos fur seals and sea lions, older offspring often attack their younger siblings, sometimes leading to the younger sibling's death (Trillmich and Wolf 2008). By doing this, the older sibling secures more parental resources for itself, at the cost of parental investment in its sibling. The mother, however, is often seen protecting the younger offspring from the attacks of the older offspring. This is in line with the theory of evolutionary parent-offspring conflict: the mother should place relatively more value on the survival and the potential future reproduction of the younger sibling than the older sibling does. In this example, evolutionary parent-offspring conflict of interests manifests as an actual conflictual interaction between a mother and her offspring. However, there are plenty of other manifestations of parent-offspring conflict that occur without overt antagonistic interactions, from the exaggerated begging for food of young birds in a nest (Caro et al. 2016) to genomic imprinting, where the expression of genes depends on which parent transmitted them (Kilner and Hinde 2012; Roulin and Dreiss 2012).

Although conflict over the distribution of resources among offspring is one of the best-studied manifestations of an evolutionary conflict between parents and offspring, it is by no means the only matter on which their evolutionary interests diverge. In fact, parents and offspring will in principle disagree about the evolutionary importance of any individuals that they are not equally related to. As a result, there will be some degree of conflict between them about how resources that enhance evolutionary fitness (i.e., survival or reproductive success) should be distributed. To account for the evolutionary importance of relatives, biologists use the concept of *inclusive fitness* (Hamilton 1964). The core idea of inclusive fitness theory is that genes indirectly affect copies of themselves if they cause their bearers to affect the fitness of related individuals (e.g., through the allocation of resources to family members). Hence, the inclusive fitness associated with a trait is not only determined by the effect that it has on the individual that carries it; we also have to add the fitness effects of the trait on other individuals, each multiplied by the *genetic relatedness* (r ; see Fig. 1) of the affected individual to the individual that carries the trait of interest.

As an illustration, consider an individual (“parent” in Fig. 1) that has to decide how to distribute an amount of resources between her granddaughter and her niece (her sister’s daughter). Her coefficient of relatedness to both these individuals is the same ($r = 0.25$; red numbers in Fig. 1), so she will place equal value on the fitness of both these individuals. Hence, she will prefer to distribute her resources such that the summed fitness of both individuals is as high as possible. For her daughter (“offspring” in Fig. 1), the calculation is quite different. From her perspective, the two individuals in question are her own daughter ($r = 0.5$) and her first cousin (the daughter of her aunt; $r = 0.125$). She places a much higher value on the fitness of her daughter than on her cousin’s fitness and does therefore not agree with her mother about how the resources should be divided between them. It is this kind of differential interest in the fitness of family members that lies at the heart of evolutionary conflict between parents and their offspring.

Kin Interest in Mating Relationships, Fig. 1 Family tree depicting a parent-offspring pair and some of their other family members. Numbers in each circle indicate the genetic relatedness (r) of the individual to the parent (top numbers, in red) and to the offspring (bottom numbers, in blue). For illustration purposes (and in line with the example in the main text), the relationship of two family members to the parent and the offspring is explicitly indicated. For example, the circle to the right of the offspring denotes an individual that is a niece/nephew from the point of view from the parent and a first cousin from the point of view of the offspring. All siblings in the diagram are full siblings; half-siblings are not included

To be clear, genetic relatedness is not the only factor that determines how individuals should allocate resources. For example, even though individuals are equally related to their parents, siblings, and offspring ($r = 0.5$ in all cases), they should not be expected to care about the survival and reproduction of those individuals equally. In their resource allocation decisions,

they should also take into account to what extent potential beneficiaries are still expected to contribute genes to future generations (this is expressed by the concept of *reproductive value*; Fisher 1930; Taylor 1990; Taylor and Frank 1996). However, since reproductive value is a property that does not change depending on the point of view of different family members, we should not expect it to affect parent-offspring conflict qualitatively.

Evolutionary Parent-Offspring Conflict over Mate Choice

Based on the previous, we should expect a conflict over mate choice to arise if different potential mates affect the fitness of relatives in different ways. Generally speaking, individuals will be more interested than their parents to attract a mate that confers fitness benefits to themselves or to their offspring. For example, we should expect them to place relatively strong emphasis on traits like parenting ability, which directly increase the fitness of their offspring. Similarly, we should expect individuals to have a stronger preference than their parents for mates that are of high genetic quality; such mates will enhance the fitness of their offspring by conferring genetic benefits (i.e., the offspring will inherit their “good genes”). Parents, in contrast, will place more value on potential mates that confer fitness benefits to other members of the family (the parents themselves and their brothers, sisters, nieces, and nephews; see Fig. 1). For example, we should expect parents to place more importance on whether a son- or daughter-in-law comes from a wealthy or powerful family; an alliance with such a family may benefit extended members through forms of nepotism and reputation. Similarly, parents may be more averse to characteristics that are considered to bring shame on the entire family (e.g., coming from a different religion or ethnic background). We should expect this to be the case if such characteristics reduce the chances of family members to obtain advantageous marriage opportunities or prestigious positions in society, thereby negatively affecting their fitness. Broadly

speaking, these predictions are in agreement with the typical observations about parent-offspring conflict over mate choice in humans, which show that parents care more about traits like family background, whereas offspring care more about traits that might indicate heritable fitness (e.g., Buunk et al. 2008; Apostolou 2010).

It is worth noting that we should not expect conflict between parents and their offspring in all cases where there is a choice between a mate conferring genetic benefits and a mate conferring nongenetic benefits. It has been argued that individuals should be more interested in genetic quality than their parents, because they have a higher genetic relatedness to their offspring ($r = 0.5$) than their parents do to their grandoffspring ($r = 0.25$; e.g., Apostolou 2007b; Buunk et al. 2008). However, as explained above, evolutionary conflict between parents and offspring is about which family members are of more evolutionary importance (and, hence, who should receive fitness benefits) – not about what kind of fitness benefits are to be allocated (genetic vs. nongenetic). When the choice is between a potential mate of good genetic quality and a mate of good parenting ability (i.e., a mate that confers nongenetic benefits to his own offspring only), there is no a priori reason to expect the parents and the offspring to disagree; both potential mates benefit the same individuals. Having said this, in cases where a “good genes” mate is compared to a mate providing benefits to other family members also, we should expect individuals to value genetic quality more than their parents do. This is consistent with empirical observations; parents value traits that might benefit extended family members more than their offspring do (e.g., family background and religious beliefs), but this is not true for traits indicating parental investment (whether a potential mate likes children; Buunk et al. 2008).

Indirect Conflict Over Mate Choice

As discussed above, parent-offspring conflict may arise because mate choice can have direct implications for the fitness of various family members.

Beside this, there are also more indirect ways in which parent-offspring conflict over mate choice can arise. How this may occur is illustrated by an evolutionary simulation model in which females and their parents (either mothers or fathers) both have an equal say in mate choice (Van den Berg et al. 2013). In this model, males vary in their “parenting quality,” a heritable characteristic that determines how much parental investment they provide to their offspring. In addition to parental investment by the males, there is also grandparental investment by the females’ parents. If parents have more than one daughter, they have to distribute their grandparental investment over the children of all their daughters. How they allocate these resources is under the control of a separate heritable locus, which allows for equal allocation (invest equally much in the children of each daughter), compensatory allocation (invest more in the grandchildren that have fathers of low parenting quality), or augmenting allocation (invest more in the grandchildren that have fathers of high parenting quality). The outcome of the model was that parents are selected to use a compensatory resource allocation strategy. In other words, it is in the parents’ best interest to compensate their daughters if they end up with a mate with poor parenting ability. As a consequence, females with a weaker preference for parenting ability in males than their sisters may end up with a relatively poor father as a mate, but do manage to attract an unequal share of resources from their parents. This way, they avoid the costs associated with being choosy, without facing any negative consequences of having a poor father as a mate. This leads to the evolution of ever weaker female preferences for mates with good parenting skills. In turn, this is balanced by a continual strengthening of parental preferences for sons-in-law with good parenting qualities. Hence, the model shows the evolution of disagreement about mate choice that increases in intensity over evolutionary time.

It is worth noting that the results of this model contrast with the general prediction that individuals should place more emphasis on mates that enhance the fitness of their offspring than their parents should. This result emerges because of the specific assumptions that are made in the model

(in this case, that parents are able to compensate daughters for choosing a bad father as a mate). This illustrates the importance of clearly delineating arguments about topics as intricate as the evolution of human mate choice. Constructing a model is valuable in this respect: it requires an explicit consideration of all assumptions, allowing for a precise examination of a line of argumentation. Using verbal reasoning alone, mistakes can easily be made, and implicit assumptions are often overlooked.

The model discussed above shows one way in which the relatively complex dynamics of sexual selection with parental involvement can indirectly result in the evolution of a conflict over mate choice. However, many other ways in which such a conflict can emerge may be conceivable. To discriminate between competing hypotheses, it is important to derive predictions that can be tested empirically. For instance, the model described above predicts a stronger conflict over mate choice between daughters and fathers than between daughters and mothers (Van den Berg et al. 2013). Empirical studies can be designed to test this prediction and can thereby either falsify or provide support for the model.

Interest of Other Kin in Mate Choice

So far, we have only discussed evolutionary conflict over mate choice that individuals may have with their parents. However, although parental interference in mate choice is perhaps the most common and best documented, parents are not the only family members that have an evolutionary stake in mate choice. Siblings, aunts, uncles, cousins, grandparents, and other extended family members also share some (but not all) genes with the individual in question, leaving plenty of scope for evolutionary conflict. However, at first sight, it seems unlikely that individuals will find allies among these other family members in the conflict with their parents. Particularly where the conflict is over fitness benefits for an individual’s own offspring (i.e., choosing a male of good parenting skills or high genetic quality) versus fitness benefits for other family members (i.e., choosing a

male with a good family background), we should expect the other family members to side with the parents, due to their differential relatedness to the parties that stand to benefit. Having said that, these other family members will not fully agree with the parents about the allocation of fitness effects either; they all have their own distinct evolutionary interests.

Conclusion

In this entry, we have seen why evolution may lead to the emergence of a conflict over mate choice between parents and their offspring. Parents and their offspring are not equally related to various family members, causing them to place different value on the survival and reproduction of these individuals. These divergent evolutionary interests can cause a conflict over mate choice, if different potential mates differently affect the fitness of family members. Mates can affect the fitness of family members in various ways, some of which are more direct (e.g., by investing resources in their offspring) and some are more indirect (e.g., by affecting the investment decisions of their parents-in-law). All else being equal, we should expect individuals to place relatively more value on mate characteristics that only improve their own fitness or the fitness of their children, whereas their parents should be expected to care more about traits that (also) benefit other members of the family. However, the complex evolutionary dynamics of parental investment and mate choice can lead to patterns that seem at odds with these predictions at first sight. For instance, in the model discussed above (Van den Berg et al. 2013), it is the parents rather than the offspring who evolve to put more emphasis on parenting qualities in a son-in-law. This example illustrates that it is important to be cautious with verbal argumentation about a topic that is as complex as sexual selection – especially in humans, where parents are also involved.

This entry has focused on examining the evolutionary causes for disagreement between family members over mate choice. However, there are many other important aspects of kin interest in

mating relationships that have not been discussed. For example, we have not considered whether we should expect conflict over mate choice to be different between individuals of different sexes. Sexual selection is rarely a symmetrical affair: in many species, there is more competition of males over females than vice versa, causing the females to be the more choosy sex. In human societies, parents exercise more control over the mating decisions of their female offspring and desire different qualities in a son-in-law than in a daughter-in-law (Apostolou 2010). Another topic we have not considered is how conflict over mate choice may affect the outcome of sexual selection. Parental influence on mate choice constitutes a sexual selection pressure; we should expect it to shape characteristics (since parents especially affect the mate choice of their daughters, we should expect this pressure to be strongest on males). In line with this, we might expect that the degree of kin influence on mate choice (which is culturally variable) affects the evolution of desired characteristics. Modeling approaches can be used to formulate predictions on the outcomes we should expect from the coevolution of mate preferences, parental preferences, and desired characteristics, depending on the degree of kin influence on mating relationships.

Definition

Kin recognition refers to individuals' ability to distinguish kin from nonkin. Kin recognition helps to avoid harmful consequences of incestuous relationships and is a precondition for nepotistic altruism.

Introduction

There are two major selection pressures for distinguishing relatives from nonrelatives. The first selection pressure is related to inbreeding avoidance. Inbreeding depression – that is, the decreased survival and fertility rates of the offspring of individuals who are genetically related to each other – is well documented among humans and nonhuman species (Charlesworth and Willis 2009). Because inbreeding has extremely harmful consequences in the case of the two most important fitness indicators, survival and fertility, natural selection should have produced strategies for helping individuals to avoid mating with close relatives.

A second evolutionary selection pressure is related to consequences on inclusive fitness (Hamilton 1964). In terms of one's fitness, it is beneficial to help close relatives, even if the costs

are high, because relatedness is also high, whereas helping nonrelatives at high cost is less beneficial in terms of inclusive fitness. By helping genetically related kin, especially when said kin are descendants, it is possible to increase the probability that one's own genes will spread to future generations. An increasing number of empirical studies of humans and nonhuman animals have provided support for this prediction, showing that individuals invest more material and non-material support toward one another according to their degree of relatedness (see Salmon and Shackelford 2011; Tanskanen and Danielsbacka 2019 for reviews).

Direct and Indirect Kin Recognition Cues

To regulate social behavior according to degree of genetic relatedness, individuals need ways to recognize to whom they are related. With the exception of mothers' relatedness to their children, all other kin relationships are more or less uncertain and need to be inferred. Because genes do not directly recognize other genes, individuals have to use cues, which help to determine whether another individual is related to her or him. These kin recognition cues can be either direct or indirect. Direct cues can be either physical or psychological, and they may include, for instance, facial and odor resemblance or personality similarity (Krupp et al. 2011). However, for the most part, humans have to use indirect environmental kin-detection cues, such as residential proximity and familial living arrangements.

Lieberman and colleagues (2007) have argued that the most important indirect kin recognition cues are duration of childhood coresidence and maternal perinatal association (i.e., an individual seeing her or his mother nurse a newborn baby) (Lieberman et al. 2007). Although the childhood coresidence cue would encompass all coresiding relatives, studies have considered kin recognition as it particularly applies to siblings. Several such studies have tested Westermarck's (1921) hypothesis, which states that coresidence during early childhood is the proximate mechanism activating inbreeding aversion among siblings, because

living very close to a person from early childhood provides a valid social cue of actual genetic relatedness. Perhaps the most prominent evidence for the Westermarck hypothesis comes from anthropological investigations that have found that childhood proximity is associated with sexual avoidance among genetically unrelated individuals who been raised in sibling-like conditions (Talmon 1964; Wolf 1995). In addition to inbreeding aversion, childhood proximity tends to be a driver of sibling-directed altruism (Lieberman et al. 2007; Sznycer et al. 2016). Finally, studies have shown support for the argument that maternal perinatal association is an important kin-detection cue among siblings; as a matter of fact, it could be even more important cue than duration of childhood coresidence (Lieberman 2009; Lieberman et al. 2007; Sznycer et al. 2016).

Although sibling recognition has received reasonably good attention among evolutionary scientists, studies detecting how children recognize their parents have been scarce (but see DeBruine 2005; Marcinkowska and Rantala 2012). In particular, there has been lack of studies considering father recognition, although most likely children recognize their fathers as the adult males living with their mothers during childhood (Haig 2011).

Conclusion

This entry has reviewed studies considering how individuals can detect their relatives. To detect kin, individuals can sometime use direct cues, such as facial or odor resemblance. However, most of the time, individuals have to use indirect environmental kin-recognition cues, such as childhood coresidence and maternal perinatal association, which have tended to be correlated with degree of relatedness in the ancestral surroundings (Lieberman et al. 2007). To conclude, empirical investigations have shown that the presence of kin-recognition cues tends to regulate human social behavior in present-day societies.

Definition

Kin recognition is broadly defined as the ability to identify or distinguish kin from non-kin using genetic similarity or any cues correlated with kinship. However, recognition does not necessarily lead to differential responses toward kin, “just as recognizing a fruit as an orange does not necessarily lead us to eating it” (Barnard 1991). Accordingly, in this chapter, the term *kin discrimination* is used to designate the differential treatment of kin and non-kin, thanks to the ability to distinguish between them. This research shows that the perception of kinship cues may trigger a heuristic process of kin recognition. Here, the

term “heuristic” could be defined as a strategy that ignores part of the information, with the goal of making decisions more quickly, frugally, and/or accurately than more complex methods.

Introduction

Kinship is special. We interact with kin differently than we do with non-kin, behaving more altruistically toward the former and more selfishly toward the latter. And the closer the kin, the bigger the investment. We also avoid sexual relations with close relatives. Because humans have lived among genetic relatives throughout their entire evolutionary history, the study of kinship in human society is a vast interdisciplinary field at the heart of social anthropology and behavioral ecology (but also, to a lesser extent, of sociology, social psychology, and family economy). The family is the primary core of social organization, and, until recently, people were only able to migrate and move to new locations very slowly. It follows that in countless social groups, kinship is inextricable from economic, political, and religious affairs. At the individual level, kinship relations are primarily social relations that influence our pro-social as well as sexual behavior. Thus, we act differently with our relatives than with individuals whom we may or may not know (friends, colleagues, neighbors, etc.).

Why Do We Feel and Behave This Way Toward Related Individuals?

Biologists have observed that kinship is involved in numerous behaviors across thousands of species, be they animal, plant, or bacterial. Kinship does play a crucial role in at least two distinct behaviors: avoiding inbreeding and altruism. Ancestrally (and even today), there was intense selection in humans to avoid mating with close relatives. Genetic endogamy has a tendency to increase the homozygosity of deleterious recessive alleles; inbred descendants are less likely to survive (primarily in utero), and when they do, they show a range of (congenital) physical (e.g., frequent immunosuppression, various

malformations) and psychological afflictions (e.g., lower intelligence levels). Given the enormous costs of consanguinity, behaviors (or motivational processes) that help prevent sexual relations among related individuals can be considered adaptive. The second behavior, altruism, is costly and generally appears ill adapted from an evolutionary point of view. Thus, altruistic acts can evolve if they bring advantages that are greater than their costs. In our human societies, there exist numerous, distinct ways in which this condition can be met, and each of its associated mechanisms is at the foundation of altruistic behavior theory. One of the most relevant mechanisms is kin selection: it postulates that we are more likely to help our close relatives (individuals from the nuclear family) more than distant relations (e.g., cousins) and non-kin, toward whom we act more selfishly. Now, notice that these are two very distinct adaptive problems: avoiding sex with our kin members and helping kin. But one common element of a solution to both is that we need to know who our kin are. Solving both of these distinct evolutionary problems requires some kind of human kin detection system, that is to say a kin recognition mechanism. But recognizing relatives is not an easy task; no method yet exists allowing humans to directly “see” another individual’s DNA and compare it with their own in order to determine their kinship relation.

This chapter argues that to gain general insight into human kinship recognition, it is necessary to take an interest in both the proximate and ultimate aspects of the different components of recognition systems. This research provides a review of the expression component, the sender mechanisms that produce kinship cues, particularly contextual and phenotypic cues, and it will also show how the receiver may interpret these kinship cues. This paper then provides a sketch of the decision-making rules/heuristic process of kin recognition, the mechanisms that enable the receiver to evaluate their likely relatedness to the sender, in order to produce appropriate behavioral outputs. The conclusions of this chapter will be that there is still room for considerable improvement in the human kin detection system.

How Do Individuals Recognize Their Kin?

How do we recognize kin? What are the psychological processes that allow us to overcome the difficulties involved in kin recognition? At first glance, these questions can appear trivial, and their answers are obvious: “We know who our relatives are because we are told [as much], because we give them names, because we have formal marriages, and because we have written records [birth registries, family records, parish records, etc.] and good memories” (Dawkins 1989). In addition, we live by relationship rules that allow us to easily identify new individuals according to different kinship types. By applying these rules, we can deduce that the son of our sister is our nephew, for example. However, verbal communication and kinship terms can also be illusory – without any real information on the links among relatives (in numerous cultures, the same word (e.g., uncle) may designate different levels of kinship or different kinship links) – but undoubtedly contribute to the systems regulating sexual preference and avoidance, along with helping behavior. Kinship terminology presents multiple traits of performative language, since the mere act of calling someone “brother” is a way to act on reality and generate a range of behaviors. Of course, the solutions (verbal communication and relationship rules) to kin recognition problems are relatively recent “contrivances” on humanity’s evolutionary timeline and are due to the evolution of language and symbolic representation ability resulting from structural neocortical development.

If linguistic and cultural information is not enough to provide a stable solution to the kin recognition problem, what then are the relevant cues?

Recognition Cues

Much of the theoretical and experimental biological research suggests that kin recognition mechanisms are also based on specific cues. Given the prevalence of these mechanisms in the plant and animal kingdoms, it is probable that they (or related processes) persist and function in humans, independently of our current additional

cognitive means of kin recognition. A reading of animal literature generally identifies two broad categories of kinship cues (Penn and Frommen 2010): the cues can result from the spatial-temporal context (that is, by contextual or indirect cues) and from phenotypic traits from the sender individual (phenotypic or direct cues).

Contextual Cues

Indirect cues are based on spatial and temporal landmarks; individuals identify as kin all those encountered in a situation or a particular place where any person is likely to be kin (e.g., individuals who are related to their mothers or who live in the same home). In humans, it has been suggested and experimentally shown that the cues reflecting spatial proximity during early childhood can be used as kinship indicators (Lieberman et al. 2007). Two contextual cues are commonly accepted as heuristic cues that signal kinship: maternal perinatal association (MPA) and co-residence duration during childhood.

Maternal perinatal association. One of the peculiarities of the human species is our long period of parental investment; the investment is mainly maternal and is essential for the survival of the child. Maternal investment starts during pregnancy and continues during breastfeeding and weaning, and the child only really becomes independent nearly a decade after birth. The close association between mother and infant (then child) provides reliable support for mutual detection between them and for each to categorize the other as a kin member. Moreover, this support can be used by other people who are present in the family environment to infer kinship. Thus, a child who has the opportunity to both observe the pregnancy of the person he/she identifies as his/her mother and to note the existence of a very close physical relationship between mother and infant can easily rely on the perinatal association cue to infer that the baby is a sibling (or to mentally tag it as such). Thus, Lieberman et al.'s study (2007) suggests that the maternal perinatal association (MPA) is a reliable cue for the recognition of siblings among themselves. The MPA is a relevant cue and a non-costly one from a cognitive point of view. Nonetheless, it is available only for people

already present in the family environment and is specific to older siblings recognizing their younger siblings as such.

Empirical support of the MPA cue comes from surveys with self-reporting responses and from physiological measurements applied to social behavior (e.g., willingness to perform altruistic behavior, real altruistic acts) and/or to the mating context (e.g., attractiveness, moral rejection, and disgust in incest scenarios). Because the MPA cue is absent for later-borns, they must employ an alternative strategy, using one or more other contextual cues to recognize "sibship" with an older brother or sister.

Co-residence duration. As the parental investment period is relatively long, the later-born is mindful that his/her parents care for and allocate their parental investment among one or more older children. Furthermore, as parental investment is costly – and therefore directed as much as possible toward kin members – the later-born may, by observing the children who receive special attention from his/her parents, reliably detect likely siblings. This spatial landmark (individuals who live together and who fully benefit from the investment of their parents) becomes even stronger when it is associated with a temporal landmark. In addition, the longer the investment, the greater the likelihood that the older child (ren) will be kin. The duration of sharing parental care, often formulated as "childhood co-residence duration," is an effective contextual cue to recognizing kinship. Initially enunciated by Westermarck in the late nineteenth century to explain what would come to be known as the Westermarck effect – children raised together during childhood tend to develop sexual aversion behavior toward one another in adulthood – this cue has been intensely studied for the past 15 years, notably with the (i) research of Debra Lieberman (see in particular Lieberman et al. (2003, 2007)) and (ii) fieldwork studies seeking to explain natural observations of inbreeding avoidance behavior in populations under specific cultural conditions.

Several studies have shown that the childhood co-residence cue (its absence vs. presence, along with its duration) is correlated with differential attitudes of participants in terms of altruistic and

sexual behaviors (disgust at the possibility of sex with a family member, choice of sexual partner) (Antfolk et al. 2012a; Lieberman et al. 2007), but also in moral opposition to third-party incest (Antfolk et al. 2012b; Fessler and Navarrete 2004; Lieberman et al. 2003) across multiple cultural groups. And the studies also revealed two more things: First, that prolonged separation between opposite-sex siblings during childhood increases their propensity for incestuous behavior. Second, that co-residence duration predicts altruistic behavior and sexual aversion even when the people involved know their siblings are distant relatives (as with half-siblings) or non-biological kin members (adopted siblings), suggesting that this cue is not affected by such knowledge (Lieberman et al. 2007). This outcome makes sense given the anthropologic observations of sexual aversion behavior in populations where young children (non-kin) grow up together (notably in the observations of kibbutz children).

Although contextual cues – perinatal maternal association and childhood co-residence duration – provide reliable information for the kinship recognition mechanism, they nevertheless have some disadvantages: (i) they are indirect cues, sensitive to the spatial-temporal environment and therefore a source of false-positive recognition errors (Park et al. 2008); and (ii) they only allow sibling members to be categorized as relatives, since the MPA cue only allows elder siblings to recognize their younger siblings, and the childhood co-residence duration cue only allows younger siblings to recognize their older siblings.

The ubiquity of kinship and its importance “are why” natural selection has selected other cues, namely, phenotypic cues, allowing us to recognize kin members in a more direct way.

Phenotypic Cues

Humans are able to use multiple sensory modalities to perceive phenotypic kinship cues in order to discriminate among familiar kin members and to recognize and discriminate among relatives in a group of unknown people. The phenotypic cues (i) must be stable through the generations, which is to say that these are partially inheritable traits but with high variability among family members

and among families themselves; (ii) the cues should be easily detectable from a cognitive point of view, by the receiver; and (iii) the cues may be more or less discreet (namely, the information may be public or private).

The workings of the phenotypic cues are fairly simple: the similarity of phenotypic traits between two people operates as a genetic similarity index. Thus, the greater the similarity of phenotypic traits, the higher the genetic similarity index, and, therefore, the higher the degree of kinship.

Although it is estimated that 40 % of sensory information comes from vision, “public” visual phenotypic cues seem quite rare, except for those shown by the face. Studies on phenotypic similarities have overwhelmingly focused on facial cues. Unlike nonhuman primates, for whom olfaction is a very powerful sensory modality, this system seems less developed in humans. However, given the prevalence, in nonhuman primates, of using olfactory clues in recognizing kinship, a few studies have shown that human body odor also works for kin discrimination. Because kinship cues are relevant when they are hereditary, phonation or acoustic similarities – copiously influenced by the environment – are rarely good candidates.

Acoustic similarity. As acoustic signals are highly dependent on the environment, their use as kinship cues may hypothetically be appropriate in two cases: (i) when the environment is uniform for all individuals (which corresponds to insular populations in a wider sense) or (ii) when the influence of the environment is still relatively weak. Although the study of the first case would require rigorous – but far from insurmountable – methodology, there appears to have been no study conducted from this angle. In the second case, several studies carried out around the perinatal period show that an individual can recognize kin by their vocalizations. Thus, mothers and fathers can reliably recognize the crying of their baby (Gustafsson et al. 2013), the limiting factor being elapsed time together. It has also been shown that fetuses may have increased heart rates when they hear the voice of their mother or father, but seem to prefer the mother’s after birth; again, the difference in exposure time to the

voices appears to be decisive. It is possible – as the first moments of any ordinary phone conversation might suggest – that in adults, the ability to recognize kinship by acoustic cues remains functional, as with other primates.

Olfactory similarity. Like the information carried on our faces, it has been shown that odors provide a variety of information on the transmitter: identity, age, sex, diet, health, but also reproductive status, etc. Furthermore, olfactory cues are excellent candidates for recognizing and finely discriminating among kin because they are known to covary with genetic kinship across a variety of taxa [Body odor is largely influenced by the major histocompatibility complex (MHC). In humans, the proteins coded by MHC genes include human leukocyte antigens (HLA) and other proteins. HLA proteins are exposed on the surface of most cells and play a substantial role in helping the immune system to discriminate between “self” and “nonself.” Greater diversity of the MHC system makes the immune system more heterogeneous and thus more adaptable in response to infection. Further, the heterogeneity of the MHC comes from the heterozygosity in our genes. Thus, two kin members, who by definition have a high proportion of identical alleles, have a highly similar MHC system.]. Thus, it has been shown that infants can discriminate among and recognize the odor of their mothers just a few hours after birth (Porter et al. 1992). Conversely, parents, aunts/uncles, and grandmothers can recognize the odor of their children, nieces/nephews, and grandchildren, respectively, suggesting an olfactory similarity among kin members across different generations and varying degrees of kinship. Siblings can recognize each other (but they do not seem to be able to recognize their half-siblings, just as parents cannot recognize their stepchildren). Studies involving the odor of identical twins even show that parents are able to discriminate between them using only this clue. Concurrently, it is important to emphasize that unknown third parties are also able to correctly match the body odor of a parent (mother and father) and their child, indicating that the detection is based on phenotypic matching. However, unknown third parties are unable to accurately

match the odor of a woman and a man living together. This latter result implies either that olfactory similarities are better reflected through genetic similarities than environmental similarities or that olfactory similarities that are environmental in origin are “masked” by the extent of gender differences. In addition, studies on identical twins where there is a genetic similarity, but also a very high environmental similarity, suggest that odors may also depend on other factors (e.g., epigenetic factors or state of stress).

It is useful to note that the olfactory similarities between two people strongly influence the expression of behavior related to kinship. The more mothers are able to recognize the odor of their infants, the more they exhibit maternal care behavior. In the same way, it has been shown that paternal investment is correlated with the olfactory similarity between fathers and their children (Alvergne et al. 2009). Other correlational studies point in the same direction: fathers feel emotionally closer to and mothers are less punitive toward their children if they recognize their body odor. The odor inhalation of same-sex individuals and those having similar HLA (which thus mimics a state in which two individuals are genetically similar) leads to different behaviors, depending on the receiver sex: it spurs women to social behaviors, particularly those tied to affinity, whereas it causes competitive behavior in men. Similar effects were also observed after the perception by participants of an oxytocin odor. Moreover, many studies have focused on the causal relations between sexual preference and olfactory similarities. For example, mutual olfactory aversion has been observed in father/daughter and brother/sister dyads at the time of menarche. A well-known study (Wedekind et al. 1995) showed that during their ovulation period, women with a natural cycle (i.e., without hormonal contraceptives) prefer the odor of men with a highly dissimilar HLA system, in order to promote HLA system heterozygosity of any offspring [although the study is mainly well known because of its result showing that sexual preferences are reversed for women taking a hormonal contraceptive (thus preferring the odor of men with similar HLA systems)].

Visual similarity. Thanks to the signals they carry, and since they are highly correlated with genotypes, faces are relevant phenotypic cues in recognizing kinship members (Kaminski et al. 2009). However, unlike studies with olfactory and auditory cues, there is little sense showing a face to a person and asking him/her if it belongs to a related or unrelated individual, with rare exceptions.

- (i) One such exception is when the spatial-temporal exposure between kinship members is short. Thus, mothers can recognize their kin among photographs of different 30-h-old infants (Porter et al. 1984). Similarly, unfamiliar and unrelated people are able to correctly match, based on facial cue similarities, a newborn with his/her parents (Kaminski et al. 2010a). Conversely, 4-day-old infants are able to visually recognize their mother, but only in cases when they experience early multisensory exposure to their mother's face and voice; facial exposure is not enough.
- (ii) A second exception is in cases when the main thrust of research is targeted at better understanding the cognitive and neurophysiological processes that are entangled in kin recognition. Thus, faces are often used to test the kin recognition mechanisms and the influence of kinship on our behavior (mating, pro-social, moral appraisal, and decision-making), but instead of directly showing the well-known faces of related members, researchers use composite faces. These composite faces enable them to experimentally modify facial cues in a very subtle manner. By altering individual facial photographs through this morphing technique, it is possible to produce an implicit yet genuine facial resemblance. To create them, the shape of a face (assume it is individual A) is delineated using a large number of facial landmarks (over a hundred). In addition, an average composite face is generated by averaging the shape and color of many same-sex images (usually around 20 faces). Then, about 50 % of the difference in shape between the face of individual A and the same-sex average

composite face is added from the same-sex composite to create a self-resembling same-sex stimuli. This relatively simple technique has been used for 15 years and has progressed along with graphics methods (see DeBruine et al. (2007) for a detailed explanation of the technique); it can be carried out using Psychomorph desktop software or Webmorph apps.

Traditionally, the method is used to test the decision-making of the participant using their own composite face (i.e., the participant and individual A are one and the same); the experimental *self-resemblance* composite face is then considered to be related, with a kinship degree close to 0.5 [*Our own face is related to (i) itself by a kinship degree of 1 and to (ii) a stranger's face by a degree of 0. The morphing of the two faces produces an experimentally altered face that is related to ours by a kinship degree of 0.5 ($r = (1 + 0)/2$)*]. More recently, several studies have dissociated the participant and the face of individual A (individual A is then the twin of the participant, or a sibling or spouse). These facial experiments reveal a modification of our behavior (especially mating and pro-social behaviors) in the presence of a "self-resemblance" composite face, but the change is condition dependent. Consequently, four major conclusions can be reached:

- (i) Be they of the same or opposite sex to the participant, the "self-resemblance" faces bring a greater trust that the composite faces are actually "other morph" and also promote cooperation strategy in economic games (especially in the public good game) (DeBruine 2005; DeBruine et al. 2011; Krupp et al. 2008). These results are consistent with predictions made by kin selection theory.
- (ii) The same-sex composite faces are deemed more attractive in the case of "self-resemblance" face than with the "other-morph" faces. However, in the opposite-sex composite face, no differences have been observed between the attractiveness of the "self-resemblance" face and the "other-

- morph” faces (DeBruine 2004; DeBruine et al. 2011). These results are also consistent with the assumption of an absence of sexual attraction or even of a sexual aversion with kin members of the opposite sex.
- (iii) Our decision-making with the “self-resemblance” composite face can be influenced by several moderators: for female participants, (a) by menstrual cycle, (b) by the emotional ties they have with their parents (primarily their father), and (c) by contextual cues, in particular the sex of their siblings and for male participants, (d) by their stress level.
 - (iv) Following studies that showed that paternal investment was positively related to both facial and odor similarities between fathers and children (e.g., Alvergne et al. 2009), several studies have used composites of an average face that looks like a child’s, in order to explore a possible effect of the sex of participant on decision-making. Results have been mixed; some studies show a detection bias by fathers, others by mothers, and several more found no detection bias.

The Heuristic Process of Kin Recognition

When we encounter a person, perception of contextual cues and/or phenotype cues (e.g., smell, voice, face, or body) induces us to process the information for kin discrimination, and possibly recognition, of the person. Cognitive processing helps to determine a kinship index, which is an estimate or a given probability that the person is kin, or not. To determine the kinship index, it is assumed that the processing is index dependent and operates from one or more implicit mechanisms, called “kinship estimators.” However, the theoretical and experimental research on these kinship estimators is scarce.

Recognition of Individuals from Contextual Cues

Contextual cues only allow siblings to be categorized as relatives. The MPA cue allows younger siblings to be recognized by their elders, while the childhood co-residence duration cue allows older siblings to be recognized by younger ones. Lieberman and coll.’s studies show that there is a

hierarchy in these two cues. Thus, maternal perinatal association overrides co-residence cues, and therefore co-residence duration does not predict aversion or altruism when the MPA cue is present. Rather, the presence of the cue is associated with elevated levels of both types of kin-directed behavior.

Because the MPA is a binary cue (presence or absence), the kinship estimator probably operates with a logical implication rule: “If I observe a strong bond between my mother and a young child (in addition to have seeing the pregnancy of my mother), I will be dealing with this child as a sibling” [Heuristic 1].

The childhood cohabitation cue includes first and foremost a quantitative parameter which reflects cohabitation duration. Studies (primarily those of Lieberman’s team) show that the greater the co-residence duration, the stronger the sexual aversion toward the individual’s elders, and the more significant the pro-social behavior toward them. These results lead to the (implicit) inference that the kinship estimator assigns a kinship index, which increases with the duration of cohabitation. In this case as well, the kinship estimator likely operates with a logical implication rule, such as “If I grew up with a child during x years, then I will treat him/her as kin, but my behavior toward him/her is weighted by the duration (x) of childhood co-residence” [Heuristic 2].

Whichever contextual cue is involved, the kinship estimator applies a simple rule to calculating the kinship index, which in both cases categorizes the person as a sibling or not, although in reality it can be a half-sibling or unrelated child, as in the co-reared peers of kibbutzim or in minor marriages in Taiwan. Such a cognitive mechanism (used to operate Heuristics 1 and 2) can then bring the individual to regulate sexual aversion toward that person and adopt pro-social behavior in competitive situations.

Recognition of Individuals from Phenotypic Cues

When the indices are direct (i.e., phenotypic cues), the appraisal of the kinship index is based on a comparison mechanism or on phenotypic matching. Two cases can result, depending on whether or not the phenotypic cues carried by

the person with whom we interact are familiar to us.

“I have already met this person!” Recognition by direct familiarization is based on learning and memorizing individual characteristics of the people we have already met. Individuals who are regularly present in our environment are categorized as familiar, and we (unconsciously) learn their phenotypic cues, a cognitive process that can then guide our behavior. For this to happen when we encounter someone, we can assume that their phenotypic cues are represented (or coded) as points in an n -dimensional space, wherein each dimension represents some physiognomic aspect (in a larger sense) of the individual’s phenotype, useful for discrimination. Each phenotype (and thus each individual) is represented by a location in space. The distance between two phenotypes represents the perceived similarity of those phenotypes (the smaller the distance, the more similar the phenotypes). Now if we meet the person again, we will compare these phenotypic cues with the known cues stored in our memory. If there is a match among cues, the individual is identified and recognized as a known and familiar person. In this case, the kinship estimator likely operates with a heuristic, such as this one “If I meet a kin member at time t and if I recognize him/her at time $t + 1$, $t + 2$. . . then I will systematically deal with this individual as kin” [Heuristic 3].

Recognition by direct familiarization is thus an individual recognition mechanism and not a mechanism unique to kin recognition (the same heuristic could apply to an enemy or selfish individual). The use of this mechanism for recognizing kin members can be seen as a by-product of a mechanism dedicated to the identification of individuals (thanks to this *bottom-up* type of cognitive processing, we can easily identify one of our former classmates, even decades after our last encounter). However, as the (familiar) environment of a young child is usually composed of kin members (parents, siblings, or in some cases grandparents), the scientific literature often classifies the direct familiarization mechanism as a kin recognition mechanism (e.g., Penn and Frommen 2010). This mechanism is highly context

dependent (mainly on population density, intensity of interactions, etc.) and represents a potential source of kinship recognition errors. Indeed, familiar individuals are not necessarily made up of kin, and unfamiliar individuals may be kin members!

“How do you recognize someone you’ve never seen?” The identification of a previously unknown person and their categorization as a kin member may occur through the use of the phenotypic matching mechanism. Let us then compare the phenotypic cues conveyed by the person to a mental image that we have built from the phenotypic cues of kin members of ours that we have previously met. Let us call this mental image Template K. The latter can be formed from two types of cues: our own phenotypic cues and those that come from our kin members.

- (a) Self-referent phenotype matching (i.e., matched with itself) is a mechanism by which an individual uses his/her own phenotype as a reference to assess relatedness with people he/she has met. The payoff of such a matching mechanism is twofold: (i) it avoids the inherent mistakes of the two other recognition systems (direct familiarization and contextual cues); and (ii) the person does not need to have previously encountered his/her kin members in order to discriminate among, recognize, and categorize all of his/her kin. This person can recognize and categorize as a kin member anyone who has a similar phenotype. However, demonstrating the workings of such a mechanism is both difficult and rare (it has been shown in certain rodents, birds, and fish), because it means that no contact with kin members can have occurred during their lifetime. In humans, it is possible, even probable, that such a mechanism exists (see Krupp et al. 2011). Conversely, visual, olfactory, and acoustic cues are suitable candidates for promoting the use of a phenotypic matching mechanism. Indeed, awareness of visual cues from our own face is quite difficult to achieve (the emergence of mirrors occurred about 8,000 years ago, and the natural reflection of our body/face in water, even when it is

still, is distorted and therefore not really relevant); so it seems unlikely that we use only these cues to build our K template.

- (b) The other-referent phenotype matching is a mechanism by which an individual uses phenotypic cues carried by various kin members (e.g., parents, siblings, grandparents, aunt/uncles) and, plausibly, by his/her own phenotypic cues. As the information revealing age and sex is typically not correlated with kinship cues, one can imagine that Template K neglects the phenotypic differences associated with this information and only keeps the relevant features from a kinship point of view. Furthermore, it is assumed that Template K can either be fixed at some point during childhood, or on the contrary, dynamic and frequently updated during life (Krupp et al. 2011). Just like with the self-referent phenotype matching mechanism, this mechanism is difficult to test experimentally.

Thus, a kin member that one has never met before can be discriminated, recognized, and categorized as such on the basis of phenotypic similarities with their previously constructed Template K (self- and/or other-referent), thanks to a process of generalization [Krupp and Taylor (2013) recently showed that for the phenotypic recognition mechanism to operate, we need additional information on the phenotypic variability of individuals in the population. Thus, this study suggests that a second template corresponding to the average phenotype of the individuals in the population (*Template A*) also be incorporated in the kin recognition mechanism. In this case then, there is twofold phenotypic matching: if the given individual is closer to *Template K* than *Template A*, he/she is thus considered kin, or non-kin in the reverse scenario, and if there is more matching between templates *K* and *A* than with the phenotype of the given individual, he/she is considered *negatively related* (see Krupp et al. (2012) for the heterogeneity of behavior with respect to these three cases: kin, non-kin, and negatively related individuals)]. The kinship estimator allowing kin recognition through phenotypic matching likely operates with two heuristics, such as “If someone

looks like a familiar kin member, I will be dealing with them as a new kin member” [Heuristic 4] and “If there is match between someone’s phenotypic cues and the K Template I built (i.e., the phenotype is a very short distance from Template K in the *n*-dimensional space), I will be dealing with that person as a relative” [Heuristic 5].

Empirical Support of Kin Recognition

As just mentioned, people can recognize kin members from five different heuristics.

Heuristics 1 and 2 apply to contextual cues and help explain our behavior toward siblings (sexual aversion and altruism behaviors). These heuristics have not been tested as such, but are used as explanatory variables (they are essentially the work of Debra Lieberman’s team) to clarify some observed behaviors, or to be used in experimental studies (e.g., surveys or physiological data studies). Although they are used specifically to recognize siblings, they also seem to influence behavior we have toward more distant kin.

Heuristic 3 is activated from phenotypic cues and is frequently highlighted in studies on individual recognition. It is a relatively simple recognition mechanism, but is not exclusive to kinship.

Heuristic 4 is a variant of Heuristic 3. Applied to kinship, it is probably very common in everyday life, but appears more difficult to prove than, and differentiate from, Heuristic 5. The Oates & Wilson study (2002), though it manipulates context cues (family names), seems to confirm the existence of Heuristic 4, showing that we behave differently toward unknown individuals who have the same family name as ours (as opposed to those with another name), behaving more altruistically toward them!

Heuristic 5 was never directly shown in the kinship context, but two lines of research suggest that it does indeed exist:

The first comes from studies involving the “self-resemblance” composite faces. As the composite faces are unknown to us, it is postulated that during interactions with “self-resemblance” faces, we will implicitly treat those faces (through the phenotypic matching mechanism) as those of unknown kin members. The

research (mainly that of Lisa DeBruine's team) has found a fluctuation in our pro-social and sexual behaviors in the presence of the "self-resemblance" composite face versus the "other-morph" composite face, confirming the hypothesis. Some studies also posit that the other-referent phenotype matching mechanism works too. However, a series of recent studies suggests an alternative interpretation of these results, different from the hypothesis above. This interpretation presumes that, in everyday life, we constantly learn the faces of people from our inner circles, be they kin or not (e.g., spouses, friends) – what we categorize as personally familiar faces. When we meet individuals who have an appearance similar to one of the personally familiar faces (like in studies with "self-resemblance" composite faces), the emotional reaction we have when we see them can influence the emotional evaluation of the face we're looking at (the "self-resemblance" composite face), through a simple transfer effect (e.g., Giang et al. 2012; Günaydin et al. 2012; Kraus and Chen 2010). This alternative interpretation of behaviors generated by "self-resemblance" composite faces is interesting and relevant, and further research involving composite face experimentation seems necessary in order to clarify the accuracy of both of these interpretations.

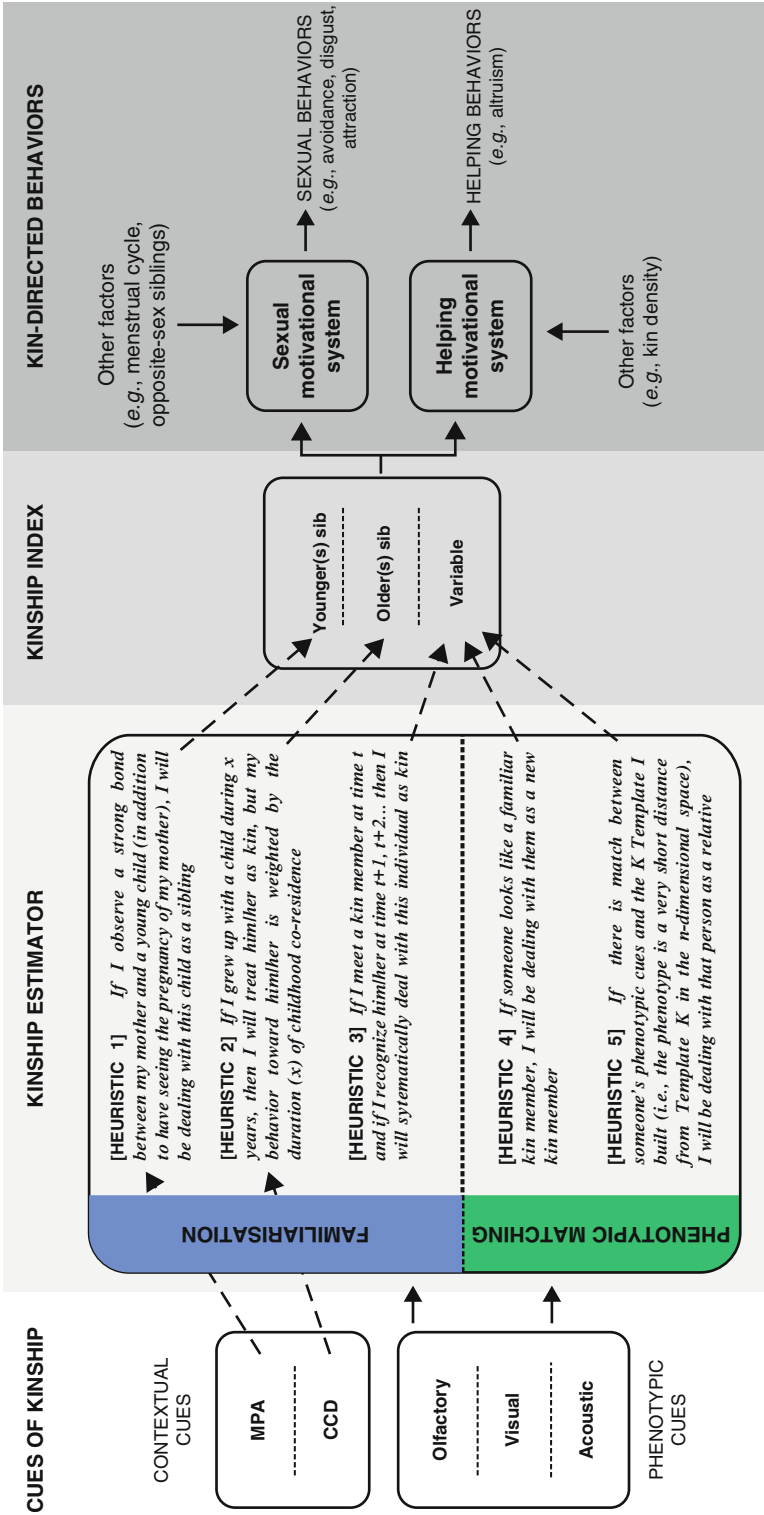

The second line of research comes from approximately 20 studies showing that we are able to, and efficient at, detect kinship among unfamiliar and unrelated individuals, through phenotypic comparison of facial cues. Our ability to recognize kin can be extended to relationships with third parties, i.e., detecting kinship in other individuals. Indeed, because we interact constantly with individuals, be they related to us or not, it is useful (and adaptive) to know who is (biologically) related to whom, in order to best adjust our behavior and ultimately enhance reproductive success (e.g., in non-human primates). Based on this postulate, various studies have highlighted our ability to detect kinship in individuals we do not know, using facial resemblance (e.g., Kaminski et al. 2010a, and one study on odor similarity,

Alvergne et al. 2009). The facial studies suggest that the aptitude is robust and is present early on in life (from the age of five under certain conditions, Kaminski et al. 2012) and that the cognitive process(es) that allow kin detection by comparing faces is not highly specialized by facial category (ethnicity, age, etc.) or kinship degree (Kaminski et al. 2009, 2010b). However, cognitive and social processes associated with this ability have received little attention up until now (see Bressan and Dal Martello 2002).

Human Kin Detection System

The heuristic process of kin recognition may be responsive to specific features in a given situation. One manner in which the situation influences the workings of the kin recognition system is by modulating the nature of the specific psychological outputs that are heightened through perception of a kinship cue. In a potential mating context, the perception of a kinship cue may trigger aversive psychological responses (e.g., disgust and reduced sexual attraction), whereas in other situations, the same kinship cue may initiate responses that should upregulate motivation to provide aid. Currently, the dominant view is that the heuristic process of kin recognition should calculate what researchers call a kinship index (Lieberman et al. 2007), an internal regulatory variable that contributes to the systems regulating sexual preference and avoidance, along with helping behavior (Fig. 1).

Indeed, as kinship cannot be directly observed, this heuristic process of kin recognition must first sort the flow of information (sensory and context dependent), but also select and save only the relevant kinship indices. Based on these cues, the heuristic process of kin recognition will produce an estimate or a given probability (the kinship index) that the other is either kin or non-kin (and if so, of what genetic distance). The thought is that the magnitude of the kinship index should reveal the degree of relatedness of other specific individuals to yourself. For example, if my kinship index for a particular person is high, as when the kinship index reveals that the female child in front of me is my sister, this index should downregulate sexual

heuristic process of kin recognition. Based on these cues, the kinship estimator will trigger one of the five heuristics and then output an estimate or given probability (the kinship index) that the other individual is either kin (and in this case, at what genetic distance) or non-kin. The kinship index will contribute to the systems regulating sexual preference and avoidance, along with helping behavior

Kin Recognition and Classification in Humans, Fig. 1 Proposed model of human kin detection system. In order to recognize individuals as kin or non-kin, people must use cues associated with kinship. These cues can result from the spatial-temporal context (contextual cues), or from phenotypic traits from the sender individual (phenotypic cues). Kinship cues will deliver their outputs to a kinship estimator, or a

attraction by activating disgust at the possibility of sex with a kin member and upregulate motivation to provide aid. The mechanism that calculates kinship indexes was named a kinship estimator (Lieberman et al. 2007). The kinship estimator, or the heuristic process of kin recognition, is likely composed of several subsystems, each dependent on one of the five heuristics of kinship and themselves dependent on the perception of the kinship cues.

Conclusion

The research reviewed in this chapter illustrates how people recognize their kin. In brief, to determine who our kin members are, we can rely on contextual cues, such as maternal perinatal association and childhood cohabitation duration, but also on more direct evidence, conveyed by phenotypes such as body odor or faces. These contextual and phenotypic cues are reliably correlated with the genetic relatedness of kin members in the ancestral environment. The kinship cues feed into a “kinship estimator” that generates a unitary “kinship index” for each individual. This kinship index then contributes, in separate systems, to regulating sexual preference and avoidance, along with social behaviors, as shown in Fig. 1. This chapter argues that the kinship estimator (or the heuristic process of kin recognition) is not a single entity, but rather consists of five distinct heuristics. Thereby, cues to kinship play a crucial role, both direct and indirect, not only in how we choose our mates but also in how egoistic, altruistic, or spiteful we are toward others.

Many questions regarding how humans recognize kin remain unanswered. The questions mainly concern the heuristic process of kin recognition and the two motivational systems that regulate kin-directed behaviors. More research (mainly in psychology) is certainly needed to clarify the nature and boundaries of the heuristic process of kin recognition. For example, to study kin-directed behavior when multiple cues of kinship are simultaneously available, or how Template K is built. Indeed, it is important to know with which people is built the template K (just

me, or my sibling, parents, and myself, or also other people present in my social environment?), (ii) when it is built, and (iii) whether Template K is static or frequently updated and so forth. But it is also necessary to delve into the neural network involved in this process (unfortunately, there are few studies available) in order to yield a complete perspective on the cognitive process. A fuller understanding of the two motivational systems, one causing sexual attraction and the other motivating help toward others, awaits additional research that better incorporates individuals’ internal state’s factors (e.g., menstrual cycle and stress level), social factors (such as emotional ties, number of opposite-sex siblings), and ecological factors (e.g., kin density in the population). Research will help us better understand the functional dissociation between these two motivational systems and how they respond to cues of kinship.

Synonyms

Inclusive fitness theory

Inclusive fitness theory and Hamilton's rule are used sometimes as synonyms but are better seen as distinct concepts.

Definition

A foundational component of social evolution theory and a broader view of natural selection where fitness effects on genetic relatives are explicitly accounted for. Kin selection is particularly well known as an explanation for the

evolution of altruism: a trait that is costly to its bearer can spread in a population if it has beneficial effects on relatives, because relatives have a higher than average chance of carrying genes for that trait themselves.

Introduction: History and the Underlying Logic of Kin Selection

“*Nature, red in tooth and claw*” wrote Alfred Lord Tennyson in 1850, in a poem dedicated to his friend who passed away at a young age. This memorable quote later found new meaning as a phrase that evokes the competitive and merciless nature of evolution by natural selection (e.g., Dawkins 1976). Natural selection does indeed seem to be an unfeeling, cruel, and indifferent process, completely detached from any moral connotations. If natural selection is about survival of the fittest, it is difficult to see how more “humane” traits, such as altruistic ones, can arise. Selfishness, where a behavior increases an individual's fitness at the expense of others, is readily explained by natural selection, but altruism is not. Altruism, by definition, increases the fitness of its recipient but decreases the fitness of the donor. Natural selection should decrease the frequency of alleles that are associated with low fitness, so how can an allele that decreases the carrier's fitness increase in frequency or be maintained in the population? Yet altruism and cooperation are commonly encountered in nature, perhaps most strikingly in the sterile workers of eusocial insects who forego reproduction entirely to help their colony.

This problem was already noted by Darwin (1859), and partial explanations were put forward by him as well as two pioneers of the mathematical foundations of evolutionary theory, Fisher (1930) and Haldane (1955). Haldane's brief verbal account came perhaps the closest to William Hamilton's later breakthrough and is quite helpful in understanding the underlying logic of kin selection: “*Let us suppose that you carry a rare gene which affects your behavior so that you jump into a flooded river and save a child, but you have one chance in ten of being drowned, while I do not*

possess the gene, and stand on the bank and watch the child drown. If the child is your own child or your brother or sister, there is an even chance that the child will also have this gene, so five such genes will be saved in children for one lost in an adult. If you save a grandchild or nephew the advantage is only two and a half to one. If you only save a first cousin, the effect is very slight. If you try to save your first cousin once removed the population is more likely to lose this valuable gene than to gain it" (Haldane 1955, p. 44).

Kin selection is a topic with copious amounts of (sometimes complicated) theory backing it up but whose underlying logic is nevertheless simple enough to grasp with minimal mathematics. Haldane's example is a useful starting point here, but as a preliminary step, it may help to review the concept of the *green beard effect* elsewhere in this encyclopedia. Recall that in the green beard effect, a single gene or a set of multiple tightly linked genes has two phenotypic effects: a trait that allows other individuals to recognize carriers of the gene (such as growing a green beard) and a behavioral trait whereby altruistic acts are directed toward others recognized as carriers. An individual with a green beard (hence also with a genetic tendency for altruism) that helps another individual with a green beard is *guaranteed* to aid the propagation of the gene for the altruistic trait, provided that the cost to the donor is lower than the benefit to the recipient. The bearer of the green beard is with certainty a bearer of the gene for altruism because of the tight link between the two. In a green beard scenario analogous to Haldane's example, a green beard gene causes its carrier to save another individual with a green beard from drowning, taking a 10% risk of dying itself while doing so. The net effect is that one copy of the gene will survive with certainty in the individual thus saved and a second copy will survive with probability 0.9 in the altruist. In other words, the expected number of surviving copies in the two individuals is 1.9, while in the absence of the altruistic act, it would be 1 (one would drown with certainty). Hence the altruistic gene can increase in frequency in the population.

Now return to Haldane's scenario where there are no colored beards, and instead an individual carries a rare gene that causes its bearer to help a full sibling: analogous to the green beard scenario, the altruist now saves its sister or brother from drowning, while again accepting a 10% risk of death (we will assume the rescuee is a sibling of similar age so that effects of age can be ignored). The net effect in this case is that the expected number of copies of the gene for sibling altruism after the altruistic act is $1 \times 0.9 + 0.5 \times 1 = 1.4$, while the number of copies that would remain in the absence of altruism would again be 1. As in the green beard case, the altruism gene can spread in the population, although selection for it is not quite as strong. Why does it spread? Being a rare gene as specified by Haldane, the altruist must have received its copy from one of its two parents (the probability of both parents carrying the rare mutation is negligibly low). The altruist's sister would therefore have received a copy of the same mutation from that parent with 50% probability (50% because the probability of one parent carrying two copies of the rare gene is also negligibly low). Therefore, even though the altruist cannot now be *certain* that the recipient of altruism will carry a copy of the gene for altruism, a sibling (or more generally, any close relative) nevertheless has an inflated probability of carrying the same mutation compared to a random member of the population.

This scenario is a simplified one, but it is intended to drive home the central idea that by helping relatives, a carrier of a gene for altruism is likely (but not certain) to help other carriers of the same gene. Because of the uncertainty, the benefit of helping must be discounted by the probability that the recipient does indeed carry the same gene (the factor 0.5 in the calculation above).

William Hamilton and Kin Selection

Although Haldane appears to have touched upon some core ideas behind kin selection and the evolution of altruism, the above verbal explanation still applies only to a very special case, and

much was left unsolved. Haldane and other authors such as Fisher described specific examples, but no one had developed a more general theory that could account for the evolution of altruism. More generally, the time was ripe for a careful reexamination of explanations for the evolution of altruistic traits poorly justified ideas of selection for the “good of the species” or “good of the group” were common in evolutionary biology (later famously critiqued by George Williams in his 1966 book – see also the section “[Kin Selection Versus Group Selection](#)”). The challenge for generalizing the theoretical foundations of altruism was taken up in the early 1960s by a British graduate student, *William Hamilton*. Hamilton took the ideas further than previous authors had and was arguably the first to fully recognize that altruism was indeed a major problem in evolutionary biology that demanded a carefully justified solution. Hamilton made the ideas hinted at by earlier authors more general and mathematically more rigorous and he also showed that under the assumptions of his model, the central results held not only for rare genes as in Haldane’s example but for any gene frequency. This property of frequency independence is important because it implies that the same rules hold from when a rare mutation initially appears in the population, all the way until it has taken over the entire population. It is not obvious that this should be the case, and Hamilton described the result as a “*gift from god*” (Hamilton 2001, p. 543). Hamilton would write multiple papers on the evolution of altruism and social behavior over the next decade (perhaps most easily found in the first two volumes of his collected papers: Hamilton 1996, 2001), with the first of his 1964 papers (Hamilton 1964a) destined to become by far the most widely recognized one, and one of the most widely cited articles in all of evolutionary biology. Hamilton’s work on kin selection was not just an isolated theoretical development; it started an entire field of research, on which many subsequent careers have been built. The following sections review some of the central concepts that Hamilton introduced, while mostly avoiding detailed mathematical treatment.

Kin Selection, Hamilton’s Rule, and Inclusive Fitness

Kin selection, *Hamilton’s rule*, and *inclusive fitness* are three of the most widely known concepts originating from Hamilton’s work, and they are at times used with much overlap in the literature. Here a separation is maintained between these notions, each with its own meaning. Kin selection (a term that first appeared in Maynard Smith (1964) and was later adopted by Hamilton and the scientific community) is the broadest of these concepts, and as will become apparent later in the section on generality, it is in fact broader than its name might suggest because it is not restricted to interactions between genealogical kin. Kin selection can be thought of as an umbrella term that covers the processes, the philosophy, and the methodology originated in Hamilton’s early work (Hamilton 1963, 1964a, b). Hamilton’s rule and inclusive fitness in turn are narrower concepts, and both are ways of encapsulating the central insights of his research.

In mathematical form, “Hamilton’s rule” was first written down in Hamilton’s very first brief article on the topic of social evolution (Hamilton 1963), but the term was apparently coined much later by Eric Charnov (1977). Hamilton (1963) originally described the rule as a “*criterion for positive selection of the causative gene*” for altruistic behavior, and this is how it is still most commonly known. However, in a more general setting, Hamilton’s rule is a criterion for natural selection to favor an increase in *any* character, not just an altruistic one. A common way of writing Hamilton’s rule is

$$-c + bR > 0 \quad (1)$$

where the classic interpretation is that if the costs ($-c$) to the donor of the altruistic act are outweighed by the benefits to the recipient (b) multiplied by the *genetic relatedness* between donor and recipient (R), the altruistic behavior can spread in the population despite decreasing the fitness of the altruist. One of Hamilton’s fundamental insights was the generalized role of relatedness in Eq. (1). Whereas Haldane (1955)

hinted at the importance that close versus more distant relatedness has, Hamilton made the role of relatedness central, mathematical, and general (Hamilton 1963, 1964a). A common misconception is that kin selection requires recognition of kin. This is not the case, and in fact, kin selection requires no cognition at all. All that is required is that interactions are more likely between related individuals, and although this could arise via kin recognition, it can also arise via limited dispersal: if individuals do not move far from their birthplace, they are likely to interact with relatives (e.g., siblings born at the same location), and kin selection can operate in absence of any active recognition.

Ultimately, Hamilton's rule arises from considering the average fitness of all individuals carrying the gene – not just the individual bearing the cost but also those who receive the benefit, and relatedness determines how likely (relative to a random individual) the recipient is to carry a copy of the gene. The three components can take on any sign, and the same criterion is true for traits that are altruistic ($-c < 0$, $b > 0$), spiteful ($-c < 0$, $b < 0$), mutually beneficial ($-c > 0$, $b > 0$), or selfish ($-c > 0$, $b < 0$) (Gardner et al. 2011). But it is the evolution of altruistic behavior where the greatest conceptual breakthrough was focused, expanding our understanding of the evolution of social behavior. In terms of the simple example in the previous section, the cost to the altruist is -0.1 (the risk of dying) while the benefit to the recipient is $+1$ (saved from certain death), and relatedness is 0.5 (full-sib relatedness). Substituting these into Hamilton's rule obtains is $-c + bR = -0.1 + 1 \times 0.5 = 0.4 > 0$, and hence the altruistic behavior is positively selected. Furthermore, because we have $-c = -0.1 < 0$ and $b = 1 > 0$, we can confirm that the act fits the mathematical definition of altruism. We can also confirm Haldane's further analysis for more distant relatives. R equals $1/4$ for a grandchild or nephew, $1/8$ for first cousins, and $1/16$ for a first cousin once removed. Calculating the value of $-c + bR = -0.1 + 1 \times R$ for each of these relatedness values in turn, we notice that Hamilton's rule is fulfilled for grandchildren, nephews, and first cousins, but for first cousins

once removed, we have $-c + bR = -0.1 + 1 \times \frac{1}{16} \approx -0.04$, so that in Haldane's example, it would not be worth saving a first cousin once removed from drowning. Hamilton's rule therefore formalizes Haldane's example in an intuitive way, while allowing the analysis of other, potentially much more complicated scenarios in the same model framework.

Inclusive fitness is a concept closely related to Hamilton's rule and an equally central part of kin selection theory, developed by Hamilton not in the first 1963 paper but in the longer and more widely known article published the following year (Hamilton 1964a). Where Hamilton's rule is a criterion for positive selection on a trait, inclusive fitness is a quantity which, in Hamilton's words "*incorporates the maximizing property of Darwinian fitness*" so that "*species following the model should tend to evolve behavior such that each organism appears to be attempting to maximize its inclusive fitness.*" Hamilton therefore intended inclusive fitness to be a maximand which helps us understand adaptation and the appearance of design in the context of social traits. Whereas Hamilton's arguments in the short 1963 paper are *gene-centric*, inclusive fitness gives selection and adaptation an *individual-centric* objective to seemingly strive towards, and thereby helps us reason about adaptation and evolution of social traits using an analogy where individuals are akin to rational agents pursuing a goal. For example, in the example of saving a sibling from drowning discussed previously, the inclusive fitness of the altruist is

$$1 - c + bR = 1 - 0.1 + 1 \times 0.5 = 1.4 \quad (2)$$

Inclusive fitness takes the actor's perspective and examines the effects that the actor's trait has on individual fitnesses, including the effect on their own fitness ($-c$) and on that of others (b) where the latter is weighted by relatedness between actor and recipient, and these are added to the baseline fitness (here, 1). In Eq. (2), $-c + bR$, which is the same as the left-hand side of Hamilton's rule is the *inclusive fitness effect*, whereas the entire expression $1 - c + bR$ is the inclusive fitness. Hamilton's rule is fulfilled, and

the trait is positively selected when the inclusive fitness effect is positive, while the eventual outcome of selection should lead to maximization of inclusive fitness. However, this maximizing property also makes inclusive fitness more controversial than Hamilton's rule. Not all researchers agree that there is any quantity that is maximized by natural selection even in the absence of social interactions, so it is not surprising that the maximizing property of inclusive fitness is viewed critically by some. The conditions under which individuals can be thought to maximize their inclusive fitness have been the focus of much research (e.g., Lehmann and Rousset 2020), and many agree that despite some limitations, inclusive fitness is a very valuable tool for understanding adaptation and organismal design, particularly when we are interested in the long-term outcome of selection determined by subsequent small changes due to mutations of small effect. Such conditions apply when we examine the origin of adaptation and the appearance of design in nature, typically arisen over a very long time in the past (see also the section on "[Criticism of Kin Selection, and General Versus Streamlined Models](#)").

Inclusive Fitness Versus Neighbor Modulated Fitness

Inclusive fitness may be the most widely recognized conception of fitness in kin selection theory, and the one that best reflects Hamilton's central conceptual breakthrough, but it is not the only one. Neighbor modulated fitness (also known as personal fitness or direct fitness) is a less widely known but nevertheless central concept of fitness in kin selection theory. It is important for multiple reasons. Firstly, the starting point for Hamilton's (1964a, 1970) mathematical analysis of inclusive fitness is in fact neighbor modulated fitness, and it is then shown that inclusive fitness is an equivalent method of analysis (see also, e.g., Birch 2017). Second, modern theoretical approaches (Taylor and Frank 1996; Frank 1998; Gardner et al. 2011) offer powerful methods for analyzing neighbor modulated fitness models – typically more convenient than the equivalent inclusive

fitness analysis (prior to the development of these methods neighbor modulated fitness was considered by many to be the more difficult modelling approach, see, e.g., Maynard Smith (1987)). Because of these developments, many theoretical kin selection analyses now employ a neighbor modulated fitness approach, although the models can typically readily be interpreted from an inclusive fitness perspective. Third, because neighbor modulated fitness is closer to the classical concept of fitness as well as the fitness concept used in other approaches to social evolution besides kin selection (e.g., the multi-level Price equation or contextual analysis), the most straightforward way to study the commonalities and equivalences of alternative approaches is to use a neighbor modulated fitness approach (Lehtonen 2020).

So what is neighbor modulated fitness? How does it differ from inclusive fitness? And how is it linked to inclusive fitness? Technical details are beyond this entry, but intuitive ideas are not. The core idea is that inclusive fitness is an actor-centric concept, while neighbor-modulated fitness is a recipient-centric concept, but in the end both count the same thing. Recall the example of sibling altruism, where one sibling saves another from drowning. To calculate inclusive fitness, fitness effects were assigned to the actors who were causally responsible for them: the altruistic individual was assigned its own fitness ($1 - c$, as altered by the cost of the altruistic action) plus the benefit (b) to the recipients weighted by relatedness between actor and recipient. The point is that the social behavior "*evolves in such a way that in each distinct behavior-evoking situation the individual will seem to value his neighbors fitness against his own according to the coefficients of relationship appropriate to that situation*" (Hamilton 1964b). This is highly intuitive and allows us to envision the evolution of social behaviors from the perspective of the individual performing them. Inclusive fitness is a quantity that is seemingly under the control of the individual performing the altruistic action.

A neighbor modulated fitness approach would instead focus on each individual in turn, examining their total personal fitness, including all effects

of their own actions *and* the actions of other individuals they might interact with. Consider, for example, the average fitness of a potential rescuee carrying the altruistic gene, swimming with her sibling. Her fitness in the simple model is 1 if she is rescued and 0 if not. What is the probability of rescue if she is swimming with a sibling? It is the probability that the sibling also carries the gene for altruism (which will make the sibling behave altruistically toward the rescuee). And by the same arguments as in the previous section, this probability is 0.5. So the diluting factor of 0.5 appears again despite the causal perspective being essentially reversed compared to inclusive fitness. The fitness of altruists on the other hand, considering a 10% probability of drowning is 0.9. If we assume that a pair of siblings always swims together, with one of them needing rescue, then the average fitness of the altruism allele is $\frac{0.5+0.9}{2} = \frac{1.4}{2}$. The numerator is the same as the result of Eq. (2). But why the division by 2? The reason is that here we are averaging over the fitness of all carriers of the allele, while in Eq. (2), we in effect computed the inclusive fitness of the altruists only. What of the inclusive fitness of the rescuee? Recall that in computing inclusive fitness, fitness effects are assigned to the individual who is causally responsible for them. The survival benefit that rescuees receive is causally attributed to the altruistic actor, not to the rescuee. So because the rescuee would not have survived at all without the altruistic act, her inclusive fitness is in fact 0 – if the benefit was assigned to both the altruist and the recipient of altruism, we would be double-counting that component of fitness. Hence the mean inclusive fitness is $\frac{1.4+0}{2} = \frac{1.4}{2}$, equal to the mean neighbor modulated fitness computed above. And it is the mean fitness of the individuals carrying the allele that matters for evolutionary change. This is closely related to an important observation made by Grafen (1982), who pointed out that there is a simple way to measure kinship effects in a measure of reproductive success: “*simply count the number of the animal’s offspring. Such a measure inevitably predicts the course of evolution for, if animals bearing an allele have more offspring than non-bearers, then the allele will spread. It*

is perhaps not commonly appreciated that this measure also includes kinship effects.” What Grafen is describing here is effectively the connection between neighbor modulated fitness and inclusive fitness. Kin selection, Hamilton’s rule, or the two conceptions of fitness that come with it are no major alterations of natural selection, despite being major alterations of how we can envision and model it. The most successful allele is selected regardless of the presence of kin effects, while the methods of kin selection allow us to reason about the outcome of selection.

Criticism of Kin Selection, and General Versus Streamlined Models

Despite a slow start after Hamilton’s initial papers, kin selection eventually became a major research theme in biology. But at the same time, it has always been the target of criticism, with many articles pointing out scenarios where Hamilton’s rule or inclusive fitness seemingly do not work or where they have significant limitations. An early but still relevant and clear account by Richard Dawkins, partly motivated by such criticisms, addresses many common misunderstandings of kin selection (Dawkins 1979). It is also important to be aware of the structure of contemporary kin selection theory, which has developed in many ways since its inception. Kin selection theory in its modern form can be thought to be composed of a very robust and general, but somewhat abstract theoretical foundation, and a streamlined and powerful set of tools for solving actual biological problems and generating testable theoretical predictions (Gardner et al. 2011). Some critical studies do not take into account these modern developments, and many criticisms are resolved when considered from the perspective of this theory base that combines generality and practicality (Gardner et al. 2011).

The most general forms of kin selection models are based on the Price equation, a fundamental equation in evolutionary theory from which many other central results can be derived (Price 1970). Hamilton was the first to publish a Price equation-based rederivation of his work

(Hamilton 1970), but the most general derivation is attributed to Queller (1992) who derived what is now widely known as the “general” model of kin selection – general in the sense that minimal assumptions are needed in its derivation. The generality of this model arises from the way costs, benefits, and relatedness are defined as linear regression coefficients. The starting point is a multiple regression model of neighbor-modulated fitness (or direct, or personal fitness) with the genotypes of a focal individual and their neighbors (or more generally, those who influence the focal’s fitness) as the independent variables. The partial regression coefficients that arise in this model are analogous to (or generalizations of) the costs and benefits of Hamilton’s rule, and genetic relatedness similarly arises as a regression coefficient. The application of linear regression may sound like the model assumes linearity, but this is not the case. The Price equation shows us that what matters for natural selection – or what natural selection “sees” is the least squares linear regression coefficient, regardless of linearity or lack thereof in the underlying processes. Hence a model of evolutionary change based on linear regression can be exact. Effects of any nonadditivity are subsumed into the regression coefficients, and defined in this way, the model components can accommodate any nonadditivity in fitness effects, or almost any other complexity we can imagine. The fact that genetic relatedness also arises as a regression coefficient which makes no reference to genealogical or pedigree relatedness per se also indicates that what ultimately matters for kin selection is genetic similarity for any reason, not just genealogical relatedness. Genealogical relatedness is however considered to be the most important driver of kin selection, while the green beard effect is responsible for notable exceptions (Gardner et al. 2011). The flipside of the generality of these models is that they are quite abstract, and it has been claimed that such a model cannot make testable predictions (Nowak et al. 2017). The most general models are in a sense “retrospective,” in that they could in principle be applied to any relevant dataset, and model parameters can be calculated from the dataset in hindsight, making the model

true almost by definition. But prediction is not the aim of this type of model, and instead the most general, regression-based formulation forms a robust conceptual and theoretical foundation and provides an organizing framework for social evolution theory, while we typically use less general and more practical methods when solving real biological problems (Queller 1992; Gardner et al. 2011; Birch 2017; Lehtonen 2020).

On the less general but more practical side, a very powerful and popular suite of methods for analyzing kin selection models was developed by Taylor and Frank (Taylor and Frank 1996; Frank 1998). One way to view these models is that they approximate the regression coefficients of general, regression-based models (e.g., Queller 1992) with partial derivatives (Birch and Okasha 2015; Lehtonen 2020), thus making it possible to take advantage of the powerful methods of calculus in kin selection models. In terms of modelling terminology, they are weak selection models where there is very little phenotypic variation in the population at any given time, thus rendering fitness differences between individuals small despite potentially strong and nonlinear relationships between phenotype and fitness. These models provide much flexibility and make it relatively straightforward to model complications such as class-structured populations (Taylor and Frank 1996). Just like the general regression-based models mentioned above, these weak selection models are neighbor-modulated fitness models: the modeler begins with an equation for the personal fitness of a focal individual, from which the costs and benefits of Hamilton’s rule arise as partial derivatives. However, the direct fitness model thus derived can typically be reinterpreted from an inclusive fitness perspective (Taylor and Frank 1996). Where the regression models focus on maximal generality on short-term evolutionary change, the weak selection methodology is best suited for analyzing the outcome of long-term gradual evolution of a character by successive small changes (Eshel et al. 1998). Although the methodology is quite different from Hamilton’s early articles, the underlying thinking and philosophy is well in line with his views: *“Most change comes, I believe, through*

selected alleles that make small modifications to existing structure and behavior. If one could understand just this case in social situations, who cared much what might happen in the rare cases where the gene changes were great and happened not to be disastrous?” (Hamilton 1996, pp. 27–28).

Kin Selection Versus Group Selection

An article on kin selection seems incomplete without some mention of the tension between kin selection and group selection, often seen as competing alternatives in social evolution theory. Central to group selection is the idea that selection favors traits that increase the productivity or persistence of groups, rather than individuals. The debate is an old one, and a culmination of it came in two books in the 1960s. Wynne-Edwards (1962) explicitly explained many seemingly altruistic traits as group adaptations, while Williams (1966) wrote a critique of prevailing views of adaptation and natural selection in general, and group selection in particular, expounding a gene-centered view of evolution (Williams’ book would become a central influence for “The Selfish Gene” alongside kin selection: Dawkins (1976)). Gene-centered thinking was similarly fundamental to Hamilton’s work, explicitly stated in his first, short article on kin selection (Hamilton 1963): “*Despite the principle of ‘survival of the fittest’ the ultimate criterion which determines whether G will spread is not whether the behavior is to the benefit of the behavior but whether it is to the benefit of the gene G .*” Kin selection provides an explicit theory of the evolution of altruistic traits that is not dependent on group selection thinking, and as such was destined to become entangled in the debate surrounding group selection.

For an in-depth account readers are referred to, for example, Okasha (2006). However, three aspects of the debate are worth pointing out: Firstly, one can quite reasonably talk about *selection* at the level of the group when carefully defined, but this does not imply that group *adaptations* can readily evolve (Maynard Smith 1987).

The reason for this is that there is typically pervasive between individual, within-group selection (Maynard Smith 1987), and selection within groups is usually not aligned with selection between groups. Second, inspired by the work of George Price and the famous equation named after him (Price 1970), Hamilton noted early on that group selection (when carefully defined, accounting for selection both between and within groups using a multilevel version of the Price equation) and kin selection are mutually compatible and mathematically equivalent explanations (Hamilton 1975), making it somewhat puzzling that debate between the two has lasted so long. Third, there are in fact several alternative mathematical ways of defining group selection (Okasha 2006), but the three major ones are all mathematically equivalent, and all three can be written using a common mathematical notation which is shared with kin selection, making it relatively simple to transition between kin selection and various forms of group selection models (Lehtonen 2020). Group selection is therefore intimately tied to kin selection and its history and development, but ultimately there is no need to view them as mutually exclusive, competing alternatives.

Conclusion

The evolution of altruism is difficult to explain, because altruistic traits by definition decrease the fitness of the altruist and should hence be removed by natural selection. Yet altruism exists in nature. Partial solutions to this conundrum were proposed, until William Hamilton published a general and mathematical explanation, now known broadly as kin selection. Kin selection explains the existence of altruistic traits but applies equally well to selfish, mutually beneficial, and spiteful traits. Central to the concept is genetic relatedness, which determines the probability that an actor and recipient share genes. Hamilton’s rule is a cost-benefit inequality with benefits weighted by relatedness that tells us when a trait (e.g., altruism) can spread. Inclusive fitness is an actor-centric quantity that is expected to be maximized by selection,

at least under some simplifying assumptions. Neighbor-modulated fitness is a recipient-centric quantity that is equivalent to inclusive fitness; it provides the starting point for Hamilton's (1964a) analysis and is central to modern methods of analyzing social evolution. In its modern form, kin selection is composed of a robust general theoretical framework (regression models) and a set of more practical modelling tools (weak selection models). Kin selection has been the source of considerable debate, and much of this debate has focused on the tension between kin selection and group selection. However, when properly defined, the two are mathematically equivalent.

[Kin selection hypothesis for male androphilia](#);
[Kin selection hypothesis for male homosexuality](#)

Introduction

The following provides an overview of the available literature concerning the evolution of homosexuality via kin selection, which has been reviewed at greater length elsewhere (for review, see VanderLaan et al. 2016, [in press](#); VanderLaan and Vasey 2014; Vasey and VanderLaan 2014). This literature pertains almost entirely to homosexuality in men, especially with regard to empirical studies. As such, this entry focuses on male, not female, homosexuality. In addition, this literature is cross-cultural in scope, and because the term “homosexual” does not always translate to other cultural settings, alternate terminology is frequently employed here. Specifically, rather

than using the term “male homosexuality,” the term “male androphilia” is used instead. *Androphilia* refers to sexual attraction and arousal to adult males; *gynephilia* refers to sexual attraction and arousal to adult females.

Below, the argument that homosexuality is an evolutionary paradox and the logic of the kin selection hypothesis as an explanation of this paradox are summarized. Evidence bearing on this hypothesis is reviewed, including tests of the hypothesis’ basic prediction, evidence of adaptive design, and developmental considerations. A recently proposed model of the evolution of male homosexuality via kin selection is proposed in light of the available evidence. Directions for future research and critiques of the kin selection hypothesis are discussed.

Homosexuality: An Evolutionary Paradox

A number of lines of evidence support the argument that androphilia in males is an evolutionary paradox. First, male androphilia has a familial component and is at least partially influenced by genetic factors. At the same time, androphilic males exhibit significantly lower reproduction rates than gynephilic males. Despite this lowered reproduction, male androphilia appears to be widespread across human populations. Lastly, archeological evidence suggests that sexual behavior between males has existed for millennia. As such, the persistence of genetic factors underlying male androphilia, from one generation to the next over evolutionary time, requires explanation.

The Kin Selection Hypothesis

The kin selection hypothesis has been proposed as one possible explanation for the evolutionary paradox of homosexuality. It suggests that androphilic males offset the cost of not reproducing directly by facilitating the reproduction of kin, who share genes by virtue of descent. In theory, androphilic males could increase their *indirect fitness* (a measure of an individual’s impact on the reproduction of genetic relatives

weighted by the degree of relatedness) via kin-directed altruism, thereby facilitating the maintenance of genetic factors underlying male androphilia in the gene pool.

Empirical Tests of the Hypothesis

The most basic prediction of the kin selection hypothesis is that, compared to others, androphilic males should be more willing to invest resources such as time and money in kin. To date, tests of this basic prediction have produced inconsistent findings across studies. Comparisons of gay and heterosexual men's willingness to allocate time and money toward their kin have repeatedly failed to support this basic prediction in several countries, including the USA, UK, Canada, Japan, Spain, and Italy.

In contrast, this prediction has been well supported in studies focusing on androphilic males in Samoa who are known locally as *fa'afafine*, a "third" gender that is distinct from the categories of "men" and "women." In several independent samples, *fa'afafine* reported greater avuncularity (i.e., uncle-like tendencies or willingness to allocate resources toward nieces and nephews) than Samoan gynephilic men and androphilic women. Given that these Samoan findings contrast sharply with those from tests of the kin selection hypothesis in several other countries, these researchers conducted a series of studies to determine whether some alternate explanation specific to Samoa explained *fa'afafine's* elevated avuncularity. Based on these additional studies, *fa'afafine's* elevated avuncularity – as opposed to the lack thereof among gay men in other cultures – does not appear to be attributable to any of the following:

- Socially desirable responding on the part of *fa'afafine*
- Greater social acceptance of same-sex sexuality in Samoa compared to other cultures
- The fact that *fa'afafine* lack direct parental responsibilities
- The fact that Samoan families typically live in close geographic proximity

The fact that Samoa is a collectivistic society

That *fa'afafine* are simply taking on the childcare role of women as part of their "third"-gender status

That *fa'afafine* have more time to allocate to nieces and nephews because they are not investing in sexual/romantic relationships

That *fa'afafine* or Samoans more generally hold expectations that *fa'afafine* will contribute more than other family members to caring for nieces and nephews

Evidence of Adaptive Design in the Avuncular Cognition of Samoan *fa'afafine*

In addition to examining alternative explanations for the unique Samoan findings, a number of studies have tested more refined predictions derived from the kin selection hypothesis to assess whether the avuncular cognition of *fa'afafine* shows hallmarks of adaptive design (i.e., evidence to suggest that the avuncular cognition of *fa'afafine* has been shaped by kin selection processes). These studies have produced a number of findings consistent with adaptive design.

- First, whereas Samoan men and women decrease their willingness to invest in nieces and nephews when they are in a sexual/romantic relationship, *fa'afafine's* avuncularity remains elevated regardless of their relationship status.
- Second, in light of the issue of paternity certainty, one can always be more confident in their genetic relatedness of sisters' children than brothers' children, and so androphilic males should favor investing in the former to maximize indirect fitness. Compared to Samoan men and women, *fa'afafine* show a bias to invest in their sisters' children, particularly when the consequences of investment are nontrivial (e.g., paying for school or medical expenses).
- Third, because younger children are especially vulnerable to mortality, an efficient means of maximizing indirect fitness would be to bias investment toward younger nieces and nephews. Compared to Samoan men and

women, *fa'afafine* are more likely to show such a bias, and this also translates into behavioral differences in terms of the allocation of monetary resources.

Fourth, as interest in investing in nieces and nephews increases, so too does interest in investing in children more generally, including non-kin children; however, dissociating one's interest toward investing in nieces and nephews vs. non-kin children would allow one to maximize investment in kin. Compared to Samoan men and women, *fa'afafine* show a greater dissociation between these domains. It is noteworthy that Canadian gay men, compared to heterosexual men, also show this greater dissociation, suggesting that the avuncular cognition of androphilic males outside of Samoa might also possess hallmarks of adaptive design due to kin selection despite the lack of support for the basic prediction of elevations in kin-directed altruism.

Development of Elevated Kin-Directed Altruism

Some studies suggest that androphilic males across cultures exhibit a disposition toward elevated kin-directed altruism beginning in childhood. Compared to their gynephilic counterparts, androphilic males in Canada and Samoa reported they experienced higher levels of separation anxiety as children. Separation anxiety is characterized by distress experienced during periods of separation from major attachment figures, who are invariably kin such as parents and siblings. This elevation in separation anxiety might reflect heightened kin attachment among androphilic males, which one would expect from a kin selection perspective given that this heightened attachment might promote kin-directed altruism later in life. Further research has shown that androphilic males' separation anxiety is driven primarily by a concern about the well-being of kin during periods of separation (e.g., worrying kin will be hurt in an accident) as opposed to other circumstances involving separation (e.g., having to go to school). This pattern is also consistent with a kin selection perspective in

that worrying about the well-being of kin would prompt behaviors to secure their well-being and thus the ability of kin to contribute to one's indirect fitness. In terms of other personality correlates, a consistent finding in this developmental literature is that androphilic males also report elevations in female-typical childhood behavior, which is positively associated with their levels of childhood separation anxiety.

The Adaptive Feminine Phenotype Model

The *adaptive feminine phenotype model* attempts to reconcile the mixed cross-cultural and developmental research bearing on the kin selection hypothesis. According to this model, a disposition toward elevated kin-directed altruism on the part of androphilic males is contingent on the concomitant expression of behavioral femininity. If so, this would explain why childhood separation anxiety among androphilic males is associated with childhood female-typical behavior across cultures. Furthermore, it would explain why Samoan *fa'afafine*, who are markedly feminine, show elevated kin-directed altruism throughout life, while gay men, who are more feminine as children but become relatively more masculine in their gender presentation into adulthood, do not.

Some recent findings are consistent with this model. First, among Samoan *fa'afafine*, childhood concern about the well-being of siblings is positively associated with adulthood avuncularity, indicating that the former does prefigure the latter. Second, among Canadian gay men, lifespan expression of kin-directed altruism appears to be linked with lifespan expression of feminine gender expression. Feminine gender expression is not only associated with their childhood separation anxiety but also with their adulthood willingness to invest in nieces and nephews. Moreover, there is a decrease in their disposition toward kin-directed altruism between childhood and adulthood, and this decrease corresponds to a concomitant decrease in their level of feminine gender expression.

The plausibility of this model is further supported by additional lines of research. To begin with, if kin selection produced an androphilic male phenotype that exhibits elevated kin-directed altruism, but only in combination with feminine gender expression, then there should be a close genetic association between these traits. Indeed, research with twins indicates that common genetic variants underpin sexual orientation and gender expression as well as sexual orientation and neuroticism (which is conceptually similar to anxiety).

In addition, if this model is accurate, then androphilic males would have had to be free to exhibit a feminine gender expression in the ancestral environment. Ethnological research indicates that sociocultural factors characteristic of ancestral human societies (e.g., hunting and foraging, relatively small group sizes) are associated with the presence of “third” gender groups similar to the Samoan *fa’afafine*. As such, it appears likely that in an ancestral context, androphilic males exhibited a markedly feminine gender expression as adults. According to the adaptive feminine phenotype model, this feminine gender expression may have then facilitated elevated kin-directed altruism – although the precise mechanisms linking feminine gender expression to elevated kin-directed altruism have yet to be identified.

Limitations

The primary criticism of the kin selection hypothesis concerns its ability to account for the persistence of genetic factors underpinning male androphilia. Some have argued that kin-directed altruism on the part of androphilic males cannot be sufficient to offset the reproductive costs associated with male androphilia. Specifically, because nieces and nephews are only half as related to oneself as direct offspring, kin-directed altruism would have to result in two nieces and nephews for every offspring foregone. The premise that such a degree of kin-directed altruism is possible has been viewed with considerable skepticism, casting doubt on the viability of the kin selection hypothesis.

That said, this critique may be overly simplistic. It is possible that kin selection processes are not sufficient to completely explain the persistence of genetic factors underpinning male androphilia, but they may contribute to their persistence at least in part. In addition, an important consideration is that population growth was only slightly above replacement in the human ancestral environment, wherein the average person produced only two offspring who survived and reproduced in turn. As such, for the kin selection hypothesis to have to be viable ancestrally, androphilic males’ kin-directed altruism would only have had to result in four nieces and/or nephews who survived and reproduced. A bias toward investing in younger nieces and nephews – like that exhibited by Samoan *fa’afafine* – might improve the survival of those kin, thus allowing androphilic males to achieve this mark. Lastly, if the adaptive design features characterizing androphilic male avuncular cognition – such as those described above found among Samoan *fa’afafine* and Canadian gay men – are indeed the product of past selection, then kin selection processes contributed, at least in part, to the persistence of genetic factors underpinning male androphilia *ipso facto*. Thus, additional demonstrations that androphilic males’ avuncular cognition is characterized by hallmarks of adaptive design would further challenge critiques about the viability of the kin selection hypothesis.

A primary limitation of the research literature concerning this hypothesis is the lack of replication studies. Although the basic prediction that androphilic males should be more willing to invest in kin has been investigated quite thoroughly in Samoa, additional tests in other populations where feminine “third” gender males exist would be valuable. Such tests are particularly relevant to evaluating the adaptive feminine phenotype model, which predicts that “third” gender androphilic males in other cultures should also exhibit elevated kin-directed altruism. To date, the kin selection hypothesis for male androphilia has only been tested in one additional population of “third” gender males outside of Samoa: the Urak Lawoi inhabiting Ko Lipe island

in the Andaman Sea off the coast of Thailand. That study found no evidence that feminine, third-gender males (known locally as *na-ning*) exhibited elevated avuncularity compared to gynephilic males from the same culture. Unfortunately, the Urak Lawoi study's value in informing debate over the role of kin selection in the evolution of male androphilia is compromised by the fact that extremely small sample sizes were employed and the statistical analyses employed were characterized by several limitations.

There is also a need to further examine androphilic males in cultures where they identify as gay men to test whether they show the same hallmarks of adaptive design that characterize the avuncular cognition of *fa'afafine*. Even though gay men do not report elevated willingness to invest in kin, they may evince some of the same avuncular cognition design features as *fa'afafine*, which would help clarify the role of kin selection processes in the evolution of male androphilia across populations.

A major gap in the research literature concerns the effects of androphilic males' kin-directed altruism on kin. If androphilic males' kin investments have positive influences on indirect fitness, then one would expect to observe increases in the quantity and/or quality (i.e., physical, psychological well-being) of their kin. To date, no research has provided such an investigation, and such tests are keys to evaluating the kin selection hypothesis.

Another aspect that has yet to be investigated empirically is the relation, if any, between kin selection processes and alternative mechanisms hypothesized to contribute to the evolution of male androphilia. A thorough description of these alternatives is beyond the scope of this piece but suffice it to say that several alternatives have been proposed. If kin selection provides only a partial explanation for the evolutionary persistence of genes underpinning male androphilia, then these alternative mechanisms might interact with kin selection processes to account for the remaining portion. Further advances in theory and research in this area are required to address these possibilities.

Conclusion

The kin selection hypothesis provides one possible explanation for the evolutionary paradox of male androphilia over evolutionary time. This hypothesis argues that androphilic males offset the fitness costs of not reproducing directly by allocating increased altruism toward kin, thereby enhancing kin's reproduction and thus indirect fitness. To date, the majority of evidence in support of this hypothesis has been found among androphilic males who exhibit marked femininity, suggesting that such gender expression might be key for facilitating elevated kin-directed altruism among androphilic males. In addition, several studies have suggested that androphilic males' kin-investment cognition is characterized by adaptive design features that are expected from a kin selection perspective. There is presently a need for further replications of this research and investigations of the impact of androphilic males' kin investment on kin in diverse cultural settings. Such work will help to clarify the role of kin selection in the evolution of male androphilia.

Kin Selective Suicide

Antonio Cabrales¹ and Gregory B. Pollock²

[Altruistic suicide](#)

Definition

Suicide committed for the benefit of kin.

Introduction

Suicide, the voluntary surrender of life (or more exactly, in evolutionary terms, the surrender of the possibility of reproduction), is the ultimate sacrifice an individual can exercise on behalf of others.

The Christian bible says “No one can have greater love than to lay down his life for his friends” (John 15:13). The pervasive evidence on this extreme kind of sacrifice poses difficulties for superficial interpretations of evolutionary theory, but can be easily accommodated by kin selection and models of local interaction.

Altruistic Suicide: From Puzzle to Redefinition

Durkheim (1897) is probably the first social scientist that dedicated serious effort to defining and understanding altruistic suicide. He starts by documenting that, against common prejudice, suicide was not unknown or uncommon among primitive societies. Rather, egoistic suicide was indeed infrequent, but altruistic suicide was “surely very common among primitive peoples.” He goes on to add that “when a person kills himself, in all these cases, it is not because he assumes the right to do so, but, on the contrary, *because it is his duty*” (Chapter 4, emphasis in the original).

This phenomenon is certainly not restricted to primitive cultures. As Gambetta (2006) shows, from the Second World War Japanese Kamikaze to modern-day Tamil Tigers or Palestinian suicide bombers – as well as present-day conflict in Syria, Afghanistan, Iraq, and Pakistan – altruistic suicide is still a common occurrence. Altruistic suicide occurs in other species, from unicellular organisms (Nedelcu et al. 2011) to genetically unrelated ant co-foundresses (see Pollock et al. 2012 for an empirical example with theoretical explanation). Kin selection predisposes individuals toward altruism, with suicidal parental sacrifice/defense of children being the most relevant case (suicidal altruism is contingent, just as parental sacrifice for young is); but kin selection does not delimit all such extreme suicidal sacrifice. Pollock and Cabrales (2008) provide other models perhaps relevant to, e.g., suicidal altruism in bombing among humans.

Evolutionarily, there is no difference between a suicide and a sterile worker, save that the latter is under indirect reproductive control via helping/

alloparenting; when a suicide also feeds back positively onto others' reproduction, it too is an indirect tool to that end. Adaptive suicide, kin selected or selected by other processes, is not an isolated event; bodily suicide in psychology, however, is generally framed as an isolated event. Thus, adaptive suicide extracts the tragedy from suicide save in a generalized parental care sense.

Altruistic suicide seems superficially incompatible with evolutionary theory. After all, if a genetic trait makes an individual disappear before reproduction, how can it hope to persist in a population? This paradox was already remarked on by Darwin in describing sterile (thus, suicidal) castes in social insects, together with the embryo of an evolutionary explanation. The first mathematically complete evolutionary model arises with the introduction of kin selection. Hamilton (1963, pp. 354–355) summarizes the point simply: “If the gain to a relative of degree r is k -times the loss to the altruist, the criterion for positive selection of the causative gene is:

$$k = \frac{1}{r}$$

Thus, a gene causing altruistic behaviour towards brothers and sisters will be selected only if the behaviour and the circumstances are generally such that the gain is more than twice the loss; for half-brothers it must be more than four times the loss; and so on.” This formulation makes suicidal sacrifice simply a special case of a more general process, although such sacrifice in social insects initially drove the theory (see other encyclopedia entries on ► [Kin Selection](#) herein for references); suicide is simply the greatest personal cost possible for an individual.

But evidence of altruistic suicide even among unrelated individuals (Pollock et al. 2012) calls for further explanation. The best existing theories employ local interaction. The basic idea is straightforward: individuals exist in space and tend to interact with individuals that are close to them. A “suicidal” gene whose acts are beneficial to spatial neighbors will also benefit in general copies of itself (thus, in a loose sense, this kind of suicide can be thought of an extended form of

kin-selected suicide). Clearly, a mutant non-altruist gene introduced within a cluster of suicidal altruists can thrive temporarily, but for the same reasons, it will soon also cluster and act mostly among other non-altruists and can collapse (or not grow) depending on dynamics at the boundary. Spatial models are usually complicated and often require a mixture of analytical and simulation techniques. Examples of such models can be found in Le Galliard et al. (2003) and Pollock et al. (2012).

Some species (e.g., some ants, Hölldobler and Wilson 1990) are able to recognize genetic relatedness almost directly through biochemical cues; humans do not. Sociobiologists saw human kin terminology as a substitute early on (e.g., Chagnon and Irons 1979). This terminology, policed, can force individuals to act on labels rather than more immediate and secure measures of genetic proximity; a biochemical cue cannot be enforced by a third party, but a kin label can. Once social life forces such reification on labels, the original kin-based anchor can be replaced – military loyalty being a prevalent and often extreme case. Once labels become primary, individuals may act on their own, living a group identity with little real referent, an adaptive failure sustained by the usual workings of labeling. Adaptation often endures such recurrent failure. Exactly how far culture can hijack processes originally compatible with genetic trajectories is an outstanding question in gene/culture coevolution (Richerson and Boyd 2008).

Conclusion

Altruistic suicide, either by direct elimination of an individual or by irreversible suppression of its reproductive ability, has been documented for a long time in humans and other organisms. Although apparently paradoxical in evolutionary terms, it can be explained easily if the beneficiaries are direct kin of the suicidal individual, and with some more work even for individuals unrelated in the usual model sense. These latter models may be genetic or a cultural analogue of genetic selection. With the latter, which surely

would include suicidal bombing altruism, one might still expect genetic bounds on realized suicide in terms of sustainable suicide.

Kindling

Androulla Ioannou and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Sensitization

Definition

Upon the cessation of repetitive strong stimulation, the spontaneous elicitation of a response occurs, in the absence of any stimulus. Also as the literal name suggests, a small spark applied to some wood will flare up and eventually grow into a big fire.

Introduction

Kindling became known to the scientific world in the late 1960s through the published work of Goddard (1967) on the neurobiology of learning and later after the application of Goddard's model on the study of epilepsy.

The Kindling Phenomenon Demonstrated Experimentally

Goddard (1967) runs a series of experiments on rats where, in order to investigate their abilities to learn tasks, he administered electrical stimulations in various regions of their brains. With daily repetition of the electrical stimuli, the rats began seizing. That response, however, was astonishing, as the administered stimuli were too low to induce seizures. Even more surprising was the final observation of the rats having unprovoked seizures, that is, seizing without

stimulation. In sensitization, repetitive stimulation produces a full response. A full response can be elicited even with lower stimulus levels than the original stimulus. It appears that a decrease in the threshold of excitability develops leading to the automatic occurrence of the response, without external stimulation. Eventually, with further repetition, the response occurs spontaneously, in the absence of any stimulus demonstrating thus the phenomenon of kindling. The changes caused by kindling seem to be long-term but they are not permanent.

Kindling is universal across species (from frogs to humans) and throughout the brain, and it was the first neuroplasticity phenomenon suggested to give information on memory processes. At a first glance, it may seem awkward to imply that epileptic seizure activity could be interconnected learning; yet, it is plausible that the diverse mechanisms constituting kindling and learning interconnect and share several common mechanisms. In effect, under this conceptualization, both kindling and learning can potentially be considered as phenomena of neuroplasticity. However, when kindling was compared to long-term potentiation as to which neuroplasticity phenomenon was more appropriate for modeling memory processes, long-term potentiation appeared to dominate, mostly because long-term potentiation was observed under normal neural activity contrary to kindling that was observed under seizures.

Further, kindling constitutes the model for the development or recurrence of medical (epilepsy) and psychiatric illnesses such as addictions and mood disorders Post (2007). Goddard's model has been referred to as the "kindling model for epileptogenesis" as it is the most frequently used model for temporal lobe epilepsy with complex partial seizures. It is used by scientists to study the effects of repeated seizures on the brain. What was demonstrated in the experiments with rats, the same applies for humans; a seizure may raise the possibility that more seizures will occur since repeated stimulation "lowers the threshold" and

paves the way for seizures to re-occur (Dennison, Teskey, Cain 1995; Racine 1978). In an attempt to better understand the occurrence of epileptic seizure, many scientists including Racine (1978) have turned their attention to the underlying mechanisms of kindling, in neurotransmitter systems and intracellular mechanisms, as well as genes.

Conclusion

Goddard's experiments suggest that the processes underlying kindling and learning interconnect and possibly have similar underlying mechanisms. Kindling is of particular importance in disorders where recurrence is involved, but its underlying mechanisms are yet to be refined by empirical investigations.

[Family Relations](#); [The Stress Response](#)

Definition

A longitudinal study was conducted over 17 years on the island of Dominica that investigated the effects family environment had on a child's stress level. It identified a number of factors such as family composition and instability within the home as key sources of stress to children.

Introduction

Humans have evolved mechanisms that function to increase fitness within their environments. The stress response is one of those mechanisms that

increases the likelihood of surviving a threat in the environment (Flinn et al. 2005). While acute stress is adaptive, chronic stress can negatively affect many aspects of health, and in the modern environment chronic stress can be caused by a variety of sources (Ader et al. 1995; Munck and Guyre 1991). Given how dependent human children are on their caretakers, they may be specifically sensitive to interactions within the family environment (Geary and Flinn 2001), and a stressful family environment may be a salient source of chronic stress to children (Flinn et al. 2005).

The Stress Response

The stress response is activated in response to the perception of a potential threat in the environment allowing the body to adapt to that threat. When triggered, it releases energy and increases both alertness and memory of the threatening event. It also suspends functions that are not immediately necessary to survival such as growth and reproductive and immune function. It does this in order to preserve energy for dealing with the threat or stressor. This response is regulated by two systems. The sympathetic nervous system secretes epinephrine and norepinephrine, and the hypothalamic-pituitary-adrenal axis (HPA-axis) secretes glucocorticoids. Cortisol is the main glucocorticoid in humans and is often released in response to an event that is perceived as unpredictable and requires full attention in order to avoid its potential consequences (Sapolsky et al. 2000).

Essentially, the stress response is a trade-off between long-term and short-term functioning. Processes essential for long-term survival (e.g., the immune system) will be suspended in order to increase the likelihood of short-term survival. This is highly adaptive in response to acute stress, but it can be maladaptive when the stress is chronic. As the stress response suppresses both immune and reproductive functions, chronic stress can result in an increased susceptibility to infectious disease and reproductive issues (Ader et al. 1995; Glaser and Kiecolt-Glaser 2014). Chronic stress has also been linked to damage in

the hippocampus and associated memory dysfunctions. The HPA-axis can be damaged by chronic stress resulting in a stunted cortisol response to stressors which is often called habituation (Glaser and Kiecolt-Glaser 2014). Pre- and perinatal chronic stress has been linked to a malfunctioning HPA-axis in both rats and rhesus macaques (Clarke 1993; Meaney et al. 1991). In humans, individuals who were sexually abused as children have been found to have damage to their HPA-axis. This is thought to be linked to the chronic stress the child experienced as a result of the abuse (Heim et al. 2000). However, it is important to note that there are individual differences in baseline HPA-axis activation and cortisol release. One study found that introverted children had higher levels of cortisol than their extraverted counterparts (Kagan et al. 1988). Regardless, there is sufficient evidence supporting the theory that consistent stressors in one's environment can result in chronic stress and that chronic stress has a negative impact on health.

Stress and the Family

While there are individual differences in response to stressors, there may have been selection pressures to evolve sensitivity to specific situations. Human infants are altricial and, consequently, require a significant amount of parental investment. Their survival, particularly during the early years of their lives, is almost entirely reliant on parental and alloparental support (Flinn et al. 2005). Alloparenting may be particularly important in the absence of maternal or paternal support (Flinn and Leone 2009). Consequently, instability and conflict in the familial environment may be a significant stressor for children.

A longitudinal study was carried out over 17 years in the island of Dominica assessing the relationship between cortisol and family environments (for reviews see Flinn 1999; Flinn and England 1995, 1997, 2003; Flinn and Leone 2009; Flinn et al. 2005). The researchers regularly observed children interacting with each other and their families in order to assess caretaking attention, family environment, daily activities, and

temperament. Researchers also took saliva samples from participants at least twice per day in order to assess baseline cortisol levels and cortisol responses.

One factor that was hypothesized to impact cortisol levels was family composition. Children who lived in a household with a nonrelative such as a step-father had higher cortisol than children who only lived with closely related relatives (e.g., parents, grandparents). Within the same household, children who were genetically related to both parents had lower cortisol than children who were not related to the father (i.e., a step-father). Children who lived in a two-parent household had lower cortisol than children who lived in a single-mother household when there was no kin support (Flinn et al. 2005). Overall, children who lived in a household with two parents, a mother with kin support, or grandparents had lower cortisol than children living in households with a step-father or a single-mother with no kin support. Additionally, children who live in houses with a step-father but who have high alloparental care had lower cortisol than those in the same situation who did not have alloparental care (Flinn and Leone 2009).

Family composition was not the only regulating factor for cortisol. Children who were part of families that were recorded as having more familial stress and conflict had higher cortisol than those who came from less stressful households. Some children from high-stress households who had experienced chronic stress also had a cortisol baseline that was below average during non-stressful times, and they had a stunted cortisol response to nonthreatening stressors such as competitive play. This is most likely due to habituation where chronic stress can damage the HPA-axis and result in a stunted cortisol production and response (Flinn et al. 2005).

There are different stressors in the environment from which the increase in cortisol could be originating from. There is the possibility that in mixed households (i.e., households with a step-parent and a mixture of biological and step-children) there is a risk for there to be higher levels of conflict or for

the children who are genetically related to both parents to receive more investment. In single-parent households, there may be less parental support or more financial issues both of which could lead to uncertainty with respect to basic needs and safety (Flinn et al. 2005). A consistent predictor of cortisol levels was the amount of maternal care. It is possible that even if the single-parent was the mother, there could still be a greater chance of stressors in the environment. This is because the mother may have to spend more time working or even allocate time and resources into finding another mate rather than investing in her children (Flinn and Leone 2009).

Conflict or instability within a family is a negative stressor. However, the stress response does not solely react to negative stressors. It also reacts to nonnegative stressors such as competitive games or situations that elicit positive emotions such as excitement. When comparing participants' cortisol responses to both negative and nonnegative stressors, there are differences in both magnitude and longevity of the cortisol spike. Nonnegative stressors were found to raise cortisol between 10 % and 100 %. However, cortisol levels generally return to their baseline within an hour. Negative stressors were found to raise cortisol 100–2000 %, and, in response, cortisol levels remained elevated for at least 24 h (Flinn and England 2003). The most common source of negative stressors was some form of conflict within the family with 19 % originating from a serious family conflict and 12 % originating from a minor family conflict. Negative interactions at home such as punishment, arguments, or change in family composition (e.g., the addition of a step-parent) consistently resulted in an increase in cortisol levels (Flinn and Leone 2009). Alternatively, positive interaction such as physical touch or encouragement lowered cortisol levels by 10–50 % (Flinn et al. 2005).

When assessing this research, there are a number of considerations such as not all children within the same household responded similarly to stressors. Some showed a spike in cortisol in response to a specific conflict within the home

while their sibling did not. This could be attributed to children's disparity in what they are sensitive to within their environment. When considering the results on family composition, it is important to note that family composition is not consistently predictive of stability within a family. There were single-parent households that were a more stable and unstressful environment than some two-parent households. Therefore, the spike in cortisol is most likely in response to instability rather than the lack of two parents. The presence of both parents or kin support can increase financial, physical, and emotional stability but that does not exclude single-parent households from being stable environments (Flinn et al. 2005).

Conclusion

The presence of chronic environmental stressors can have negative effects on the health and well-being of individuals (Ader et al. 1995; Glaser and Kiecolt-Glaser 2014). Children, in particular, seem to be sensitive to stressors such as conflict or instability within their family environment. The lack of kin support, the presence of a step-parent, or a household with a high amount of conflict can result in children having elevated cortisol or a dysregulated HPA-axis (Flinn and Leone 2009; Flinn et al. 2005). Considering the health repercussions associated with chronic stress, this research suggests the importance of focusing on the home environment when attempting to reduce stress in a child's life.

Introduction

Recent changes in definitions of the family bring forth issues related to defining kinship and concerns over the positive contributions of kinship. Many have alluded that strong kinship is limited to families in developing nations and in light of the lack of societal emphasis on Kin, the topic remains empirically unexamined.

Contributions of Kinship

The family performs crucial functions and satisfies many human needs, such as the provision of economic security, socialization of children, a satisfaction of sexual needs, and love and warmth (Wolf 1966; Choldin 1973). Although other societal institutions can gratify these needs, the family as an institution can execute the above-listed tasks with modest costs and in a more competent manner. Immediate family members and Kin are more competent as they are genuinely concerned and committed, and culturally obligated to carry out these tasks to the best of their ability.

Applications of the concepts of generativity to kinship clarify the rationale behind genuine

concerns, significant investments, and firm commitments of family members towards each other. Since the sense of generativity creates a need to focus on others, as a consequence, it pushes individuals to guide and support future generations. Generative individuals' guide and support future generations by nurturing, teaching, and passing on cultural symbols/traditions (Erkison 1950; Kotre 1984). It is essential to state here, that the process is highly beneficent to both members as acts of generativity are the developmental needs of one member, while the other member is benefited by the support he/she receives.

Correspondingly, Kin are not only "mentors (teach skills, provide guidance), keeper of meaning (preservers of family traditions, family historians), intergenerational buffers (can intercede on behalf of parents, emotion work and resolution of conflict), but also, fellow travelers and companions (help to cope with significant life events, social and emotional support)" (Milardo 2009, pp. 16 & 17).

Besides direct benefits, kin membership provides a sense of identity in the world; for example, the last name may suggest a strong lineage. Daly, Salmon, and Wilson (1997) suggested that belonging to a particular clan is a universally stable attribute. Therefore, for many, the kin membership helps to maintain a sense of higher and more positive reputation in comparison to others, aka, higher social credibility and social capital as members are obligated to share their prosperity (Dasgupta 2005). Nevertheless, how does one achieve social credibility because of the family lineage is a logical question.

Kellerhals, Ferreira, and Perrenoud (2002, p. 215) described the social mechanism of identity transmission among Kin. The researchers suggested that the successful identity transmission process requires three prerequisites. These prerequisites are (a) "normative reference marks such as occupational class, symbols of the family emblem, family name or value code and more, (b) transmission channels such as strict and well-differentiated family codes, intimate exchanges and more and (c) types of cohesion of the actors who personify these reference

marks and who are involved in the transmission channels. These include hierarchy between members (patrimony), family boundaries, and more.” Furthermore, in the process of maintaining membership, kin members develop “social synchronization” (Wolf 1966, p. 9), which is consequential in the development of trust and a sense of cooperation among Kin. Thus, on the one hand, strong lineage and social goodwill offer social credibility, yet on the other hand, it demands harmony and trust among its members.

Despite the significant contributions to human development, research on kinship is underdeveloped and is limited to the caregiving of the elderly (Milardo 2009). Therefore, there is a need to explore beyond caregiving and understand the obligatory and non-obligatory roles of extended family members and their motivations to perform these roles. Hence, the current article reviews the contributions of emotional closeness in strengthening the relationship among Kin.

Emotional Closeness and Kinship

Emotional closeness, although not well- defined in research, consists of a shared sense of security, comfort, trust, and care for another individual (Korchmaros and Kenny 2001; Lee et al. 1990). Kin are defined as individuals related by birth, common ancestry, marriage, or adoption. When applied to kinship, emotional closeness is associated with higher altruistic behavior and assistance (Bell et al. 1995; Clark and Mills 1993), better communication (Roberts and Dunbar 2011), and stronger commitment and investment (Antfolk et al. 2017). All of the above stated variables in relationships can be a lifesaver at the time of crises.

Despite the merits, emotional closeness among Kin can be a function of genetic relatedness, age and stage of development, gender, residential proximity, filial piety and inter-generational solidarity, and more. Given below are some of the factors that moderate or mediate emotional closeness among Kin.

Factors that Impact Emotional Closeness and Kinship

Genetic relatedness. Hamilton (1964) proposed the Kin Selection Theory, which is the foundation of social behaviors and its applications by social psychologists. He proposed that genetic relatedness is the basis of altruistic behaviors towards family members. His theory was later tested and confirmed by several researchers. For example, in a comparative study of full, step and half-siblings; sibling relationships were found to be less intense among step and half-siblings than full-sibling relationships (White and Riedmann 1992). Likewise, Pollet (2007) found that in cases of paternal half-siblings and maternal half-siblings, despite being raised together, half-siblings had a lower degree of an investment than full siblings thus concluding that stronger genetic relatedness is more critical than residential proximity. Recently, Tanskanen and Danielsbacka (2014) applied the Kin Selection Theory to nieces and nephews and found similar findings. The researchers reported that uncles and aunts would meet more frequently with their children of full siblings than half-siblings.

To add to the body of works on genetic relatedness and altruistic behaviors, Daly, Salmon, and Wilson (1997) and Neyer and Lang (2003) suggested the mediating role of emotional closeness between the two variables. Both sets of researchers suggested that although close relationships are based on emotional closeness and connections, but the connections often correlate with genetic relatedness and the concept of near and far relatives. Similarly, Korchmaros and Kenny (2001) tested a model and found that altruistic behaviors facilitate higher perceptions of emotional closeness by mediating the effect of genetic relatedness on altruism. Therefore, we are benevolent to individuals who show connection, cooperation, and solidarity, but most individuals who exhibit these behaviors are also genetically related to us.

Hence, the above researchers provided evidence for the commonly used phrase, “Blood is thicker than water”. However, the extension of the Kin Selection theory does not sufficiently resolve

the question- why, despite the rivalry and competition for the same resources, family members support each other when in conflict with non-family members. Perhaps cultural rules of kin obligations are integral variables.

Life-course development and gender. Especially for females, kinship care begins early in many families with sibling care. In many cultures, especially non-industrialized, girls begin to contribute toward domestic chores, childcare, and the economic well-being of the family at an early age and become mothers helpers/alloparents (Hames and Draper 2004; Quinlan et al. 2003; Bove et al. 2002). Even in industrialized societies, despite the cultural differences; siblings are generally the first friend and mentors who continue to stay part of the social network of their younger siblings for the rest of their life (Cicirelli 1985, 1994).

Once in their young adulthood and adulthood, personal and professional trajectories of an individual offer additional opportunities for building new relationships or renew or renegotiate past relationships. Marriage of self and their siblings extend an individual's kin network resulting in becoming parents, son-in-law, daughter-in-law, aunt/uncle and brother-in-law/sister-in-law (Milardo 2009). The new relational experiences and changing relational landscapes along with age and stability in professional life, may demand a significant investment of effort and time and therefore, commitment. Nevertheless, investment and commitment are not all biological and the strength of investment and commitment are often conflated with the cultural feelings of solidarity & obligations, the similarity of attitudes, perceptions of support, and residential proximity (Milardo). To complicate the matter further, belonging to a female gender can make someone a normed Kin keeper. Perhaps that is why researchers have noted the laterality effect i.e. female Kin such as sisters, maternal grandmothers, and aunts (normed kin keepers) are more invested in raising their siblings, grandchildren, and nieces and nephews (Parent et al. 2013).

During middle adulthood and older years caring for parents and dealing with parents' poor health, disabilities, and death (Lachman 2015) along with professional and nuclear family

commitments become part of life. Furthermore, declining physical and mental health of self or parents may mean additional financial and caregiving pressures (Lai 2012). For example, *filial piety* and *respect for elders* are the underpinnings of grandparents and grandchildren bond in Asian cultures (Yee 2008). Nevertheless, many individuals in their old age are also liable to care for their grandchildren and shift their role from being a grandparent to a parent (Newman 2004). These additional and non-normative responsibilities may decrease the quality of care provider's social relationships and marital satisfaction (Minkler et al. 1992; Jendrek 1993) and result in poor mental and physical health of grandparents (Goodman et al. 2008).

Nationality, cultural and ethnic values. Cultures play a vital role in describing and sanctioning individual expectations, rights, and duties from other family members. In cultures with strong kinship orientation, kin members are considered a form of social insurance at the time of crisis. Nevertheless, this social insurance is built upon, loads of time, energy, and efforts of all kin members with an absolute goal to sustain relationships at all costs. The goal to save the relationship at any cost can be perceived as a burden by individuals from individualistic orientation.

To elaborate, Kim and McKenry (1998) compared the social activities of African Americans, Asian Americans, and Caucasians adults after controlling for their socio-economic background. The researchers found that Asian Americans owing to their collective orientation, were more likely to spend a social evening with their friends and relatives at home and participate in a nationality group event. African Americans were more likely to attend a church-related social event and Caucasians and younger African Americans were more likely to go to a bar or tavern for group recreation.

In terms of reliance for support, African Americans mothers leaned on extended family networks extensively for financial, physical, and emotional support in the absence of the child's father (Sudarkasa 1996). Expectations of support from the father of the child were found to be remarkably low. Perhaps, women hinge more on

the maternal side of the family for support as African American men have a higher rate of unemployment and incarceration (Haxton and Harknett 2009).

Despite the differences in reliance for support, Kin support serves important functions in African American families. Hall (2007) examined the effects of kin and fictive kin support on the development of resilience among African American children of alcoholic parents. Hall reported that children of alcoholic parents in his sample experienced physical, emotional, and financial distress and therefore, the positive support from Kin is a much-needed factor to develop resilience in at-risk families. Since positive support promotes attachment, it detracts children from risky behaviors and enhances their chances to succeed academically and in intimate relationships.

Likewise, Hispanic families have a stronger family orientation than Whites and reported higher intergenerational contact and emotional support (Garcia 1993). However, in contrast to African American families, support is expected from both sets of grandparents (Haxton and Harknett 2009).

Despite the contributions of kinships in families from developing countries and minority groups, many authors alluded to the small role of Kin among families in industrialized nations such as the US (Rodman 1965; Parsons 1943). According to the authors, in the US, the conjugal family is emphasized, and the family-of-orientation of both spouses play an insignificant role in providing economic security and socialization of children. Perhaps that is why, unlike developing nations, they also receive less physical care from their children in old age and rely more on community resources.

European countries. To test the above proposition of weaker kin ties in western nations, Höllinger and Haller (1990) examined the decreasing role of kin ties and the increasing role of non-kin ties among seven European countries. The seven countries were Australia, Austria, Britain, West Germany, Hungary, Italy, and the US. The authors collected data on almost 10,000 individuals and the sample size ranged from 1,000 to 2,800 individuals from each country. The goals

of the study were to compare the frequency of contact between Kin and non-Kin and ascertain the differences in perceived social support.

The authors found that the frequency of contact with Kin was higher among Italian and Hungarian families than American and Australian families. Individuals from Austria, West Germany, and Great Britain were in the middle, with Austrians being closer to the Italian/Hungarian pattern and Brits being closer to the American/Australian pattern. The findings confirmed the effect of the modernization and the diminishing role of kinship in developed countries. It was concluded that Hungary and Italy suggested some evidence of a focus on family and kinship as it had a lower GNP in comparison to other nations in the study.

Nonetheless, in terms of social support, Höllinger and Haller (1990) concluded that close Kin are sought for help in emergencies, even in developed countries. Thus, in the sample from Britain and Germany, even though the spatial distance from parents was more substantial than from Italy and Hungary, the children remained emotionally connected to their family of orientation and would often seek emotional assistance. Finally, Höllinger and Haller (1990) concluded that, except for Italy, the importance of friends in people's social support networks is inversely proportional to the importance of extended kin.

Non-European countries. Among specific Inuit groups, children are expected to carry out kinship obligations from a very young age, and to jump-start the process, adults help them listen to and recite the terms for their kin in infancy and toddlerhood (Douglas 2009).

Harris and Shaw (2009), in their chapter titled - *Kinship obligations of Pakistani immigrants in Great Britain* suggested that kinship relationships in Pakistani immigrant families are complicated, hierarchical, patriarchal, and densely layered with contradictions. Consequently, even though family members may have divergent viewpoints and life goals, they will continue to satisfy the normative expectations and obligations of the kinship from their native culture.

The authors clarified that unlike western cultures, among Pakistani families, the term closed family, i.e., "*gharwale*" includes grandparents,

uncles and aunts and first cousins. The term extended family, i.e., “*Biradari*” includes other individuals who are blood-related, but are not co-residents (p. 129). Despite the larger spatial distance due to immigration, kin members are still obligated to support each other at the time of need.

Evidence of the above necessity to meet kin obligations despite the residential proximity was further presented by Kalra (2008) in case of marriage. Kalra states that Muslims practice clan endogamy and therefore, cross and parallel cousin marriages are normative, permitted, and preferred in Pakistani families as it encourages kin affiliation and bonding. Through marriage and procreation, the kinship is further strengthened as all the “all networks are extremely close-knit and intuned.” However, immigration and exposure to western cultural values pose unique problems. Pakistani immigrants in Great Britain succumb to kin pressure and often marry their children with their nieces and nephews in their native country. Alternatively, they will be considered “anglicized” and socially reprimanded for forgetting their Kin (pp. 35 & 33).

Recent Trends in Kinship Patterns and Care

Wachter (1997) lamented that all kinship ties, especially step ties are getting weaker, leading us to inaccurately assume that kinship ties play a nominal role in an individual’s life. He further cautions that our interpretations of kinship and its contributions cannot be based on current trends as the definition of the family has changed significantly over the years. He further adds that in reality, recent changes in marriage, divorce, remarriage, cohabitation, shared custody and more have contributed to broader kinship and more inclusive families that consist of ex-spouses, step & half-siblings, close friends, neighbors, and even animals. Even today, the sense of security that Kin/family members provide along with positive memories is emphasized in families.

Interestingly, what Wachter stated had been a common practice in other cultures for centuries. For example, among Malays co-residence and sharing food from the same hearth creates kinship ties (Carsten 2004).

Nevertheless, one category that is new and has been created because of medical advancements is donor created families. Cahn (2012) suggested that millions of families have been created from donated sperms and eggs, yet the legal status of these families may not be at par with other families in the light of shared genes, but lack of connections and reliance for support. Although Donor Sibling Registry has created some connections, yet most individuals born out of donated egg or sperm, want to understand and are curious to know more about their biological roots. In the absence of such information, they experience a sense of loss (Turner and Coyle 2000). According to Cahn, who is the parent/family of the donor offspring and the possibility of emotional connections with the donor family can present some unique and complex legal issues.

Social Programs, Family Policies, and Kinship

Kinship care is universal with siblings raising siblings, grandparents raising grandchildren, daughters-in-law/daughters caring for their parents and parents-in-law, and spouses caring for each other in old age or disability. To illustrate further, in the US alone, approximately 2.6 million children lived with a relative who is not a biological parent (Kids Count 2018). The reliance on growing numbers of children and adults on kin members for care brings forth complicated relationship-based care and resilience issues for both care recipients and providers (Connolly et al. 2017).

Most of the time, kinship care is arranged by the child welfare agencies and kin care providers are permitted to make academic, legal, and medical decisions (Rubin et al. 2017) for their adopted children. Many of the relatives who are now legal guardians may have inadequate financial resources and education or training to raise

children or may additionally have mental health issues. To combat the issue, Rubin et al., recommended that the American Academy of Pediatrics and policymakers recognize kinship care and their unique needs in the medical field through training of their medical residents and providing access to community resources. Likewise, Winokur, Holtan, and Batchelder (2018) recommended training, supervision and licensing of kin caregivers to improve permanency and safety of young care recipients.

Bell and Romano (2017) reviewed 54 studies to examine the impact of kinship care on child outcomes in comparison to other placement types (e.g., foster family) in terms of permanence of care and safety. The authors reported that although the positive outcomes diminish over time, most studies suggested that children in kinship care experience a more stable childhood with fewer transitions to receive care from other families and a lower likelihood of adoption in comparison to children in foster family homes.

Future and Limitations of Kinship Research

There had been several limitations and recommendations to improve kinship research. Given below is a very brief account of some recent work.

In terms of theoretical models, Aktipis et al. (2018) criticized traditional models of kinship and recommended the applications of the fitness interdependence model. The model successfully integrates the variations in positive correlations between both kin and non kin and altruistic behavior. The authors suggested that mutual dependence among members gives rise to altruism regardless of genetic relatedness. Similarly, Itao and Kaneko (2020) attempted to understand the emergence of kinship structures (such as generalized exchange and restricted exchange) and the incest taboo through the applications of the degree of cooperation and mating conflict model among indigenous groups. The authors concluded, “incest taboo emerges when the necessity of cooperation, the conflict for mating, and cultural

similarity across generations are sufficiently large.” (pp. 23–83).

In terms of recommendations for future research, Itao and Kaneko (2020) noted that future research must focus on each indigenous group separately. In addition, Furstenberg (2020) recommended that kin relationships and connections can be studied beyond tangible support kin provide to each other, as it is especially relevant in higher income families.

Conclusion

Even though, kinship and emotional closeness remain unexplored in the US, research from other cultures suggests that kinship contributes positively to human development and therefore, there is a need to integrate extended family members in family interventions and social law and policy.

Kinship Distinctions According to Generation

Synonyms

Distinction according to genealogical level

Definition

“Kinship distinctions according to generation” refers to linguistic distinctions between kin who are of the same generation and those who are in the generations above or below you. These distinctions exist, to some extent, in all languages. For example, in English, we distinguish three basic generations of kin: ego’s (or the speakers) generation, *brother*, *sister*, and *cousin*; the generation above ego, *mother*, *father*, *aunt*, and *uncle*; and the generation below ego – *son*, *daughter*, *niece*, and *nephew*. To refer to other generations, we can append the prefix “great-” or “grand-” to these basic terms. These generations are often referred to as G^{+1} for the parental generation, G^0 for ego’s generation, and G^{-1} for the generation of

ego's children. This system is extensible, so G^{+2} would refer to ego's grandparental generation.

Introduction

Generational distinctions are found to some extent in all languages and are one of Hérítier's "first fundamental laws of kinship" (Hage 1997). Since kinship systems are largely focused on reproduction and dependency, it is natural to distinguish carers from those who are being cared for (Greenberg et al. 1978). It is also common to make more distinctions in the descending generation, or generation below, than in the ascending generation (the generation above); however this is not the case in English.

Generational distinctions are arbitrary, as people within a society are born and die continuously, and not in distinct sets (Parkin 1997). Equally, men (and to some extent women) can have children over a long time span, meaning kinship ties may often be at odds to what is commonly thought of as generations, people of similar age. For example, if a grandfather has a son after the birth of a grandchild, this child's uncle will be younger than them. Kinship distinctions according to generation, then, could be more accurately described as genealogical distinctions, as they are more directly related to links between relatives than relative ages.

An interesting generational feature, exemplified by the Kariera of North Western Australia, is that of alternating generations (Parkin 1997). This is where kinterms are repeated across generations, often at G^{+2} and G^{-2} . This would mean that the terms used for grandparents are the same as those used for grandchildren. Alternating generations have also been observed between G^{+1} and G^{-1} or between ego's generation and some members of G^{+2} or G^{-2} . Explaining why this feature occurs has long been a puzzle for anthropologists. Possible explanations for why this feature occurs are symmetric prescriptive marriage or a belief in -grandparent-grandchild reincarnation (Hage 1999). However, there is no consensus on the sociological explanation of alternating generations.

There are some special cases where generational distinctions do not occur, and kinterms cover multiple genealogical levels. This is called the *skewing principle* or *generational skewing* (Godelier 2012). An example of this is when people in G^0 are treated as or at least categorized as G^{+1} relatives or higher. This famously occurs in Crow and Omaha systems. These systems are strongly tied to societies that prioritize matrilineal or patrilineal descent patterns (Keesing 1975). Crow societies are associated with matrilineality and use a classificatory term for brother's son, mother's brother's son, and mother's mother's brother's son (Stone 2014). All of these relatives are outside of the matriline and grouped together, using a term that could be broadly interpreted as "son's of men in my matriline." Similarly, within Crow, there will be one term for father's sister, father's sister's daughter, and father's sister's daughter's daughter or "women of father's matriline." Omaha is the patrilineal equivalent of Crow and tends to use a classificatory term for sister's son, father's sister's son, father's father's sister's son, or "son's of women in my patriline." However, there is no consensus on why this principle exists, as it does not appear to solely depend on lineage patterns.

Kinship Distinctions According to Sex

Sam Passmore

University of Bristol, Bristol, UK

Synonyms

[Gender distinction](#); [Relative sex distinction](#)

Definition

Most if not all languages make distinction between kin according to gender: for example, in English, mother versus father, brother versus sister, and uncle versus aunt (Greenberg et al. 1978). In each of these cases, the distinction is applied to kin who are otherwise of equal genealogical distance to the speaker (ego). Cousin, in English, is an example of when kin are not distinguished according to gender.

Introduction

Gender is used to distinguish kin in one of three ways: gender of relative name, speaker's gender, or gender of the linking relative (Kroeber 1909). Gender of relative is when the kin term used depends on the gender of the person being referred to; in English, female relatives include *sister*, *mother*, and *aunt*, but not *cousin*, which could refer to a male or female relative. When kin terms depend on the sex of the speaker, the terms used by a man would differ to those of a woman. A special case of this distinction is when kin terms denote that the referent is the same or

different gender to the speaker. This is common in the Pacific; for example, in Tongan, a man would call his elder brother *ta'okete*, and a woman would also use this term for her elder sister. This term could be translated as "sibling of the same gender, who is older than me." The third way gender is used to distinguish kin is through the gender of the linking relative: this is when the term used for a relative that is connected through another relative (e.g., uncle is connected to ego through their mother or father) is determined by the gender of that connecting relative. In English, the term "uncle" makes no distinction between mother's or father's brother, so the parent's gender does not have an influence on kin terms. However, if gender of the linking relative is a constraint on the language, different terms will be used for the mother's brother and father's brother. This distinction is also how cross-cousin terminologies are generated, where parent's siblings of the opposite gender's children are given different terms to parent's siblings of the same gender's children.

Distinctions of gender are overwhelmingly common across languages, so it is of interest when they do not occur. This is the case in Malay, where marking relatives by gender in ego's generation is only reckoned through use of an optional suffix (Banks 1974). However, the core terms, *adek* and *anak*, refer to older or younger siblings regardless of gender.

Discussion

Why gender distinctions occur (or do not occur) is an interesting question and one that is not fully resolved. Possible reasons for distinguishing gender between equally distant relatives could relate to societal gender biases or sexual reproduction, although other explanations are possible (Fox 1967; Keesing 1975). Societal gender biases are when women and men have specific roles or are treated in particular ways within a society, which may be reflected and reinforced through language. An example of this is the comparison of mother and father in English, which have clearly defined parental roles in society (Stone 2014). Other

hypotheses suggest gender-biased inheritance patterns, household roles, or more broadly gender roles may encourage gendered kin terms. Sexual reproduction and gendered kinship terms can relate to one of two possibilities. Firstly, it posits that the biological nature of parenthood leads to gendered distinctions at least within the nuclear family. However, this hypothesis is heavily contested and does not explain many of the cultural differences between men and women (Collier and Yanagisako 1987). Secondly, if a society practices cross-cousin marriage, it makes sense to distinguish those cousins who are marriageable to those who are not. In societies where the language only reckons the gender of the referent relative, then it is necessary to also separate marriage partners for male or female egos. However, within each of the possible explanations for kinship distinction for gender, there are numerous counterexamples. It seems unlikely that a universal explanation for distinguishing kin by gender will ever be established.

Kinship Is Central to Self-Concept

Shane Westfall, Rebecca Barton-Stewart and Ryan L. Desmond
Western Wyoming Community College, Rock Springs, WY, USA

Synonyms

[Self-concept and family](#); [Self-concept determined by relatives](#)

Definition

Self-concept refers to an individual's collection of thoughts and beliefs about themselves. It is comprised of multiple mental templates that the individual uses to organize information about the world. These templates include information about the groups one is a member of and central to these are the bonds of kinship.

Introduction

Self-concept describes an individual's collection of thoughts and beliefs about themselves. These self-perceptions involve empirical evaluations, identification with groups and social roles, judgments of personal attributes and abilities, and a concept of the ideal self. Self-concept begins development during infancy and is considerably influenced by an individual's interactions with significant others throughout the lifetime. As such, a person's self-concept continues to develop and change as one ages. This is done through the formation of cognitive structures representing the individual's organization of past experiences. Although often flawed, these *schemas* are mental templates that individuals use to organize and store information about the world (Bartlett 1932). Central to the development of the self-concept are self-schemas, the mental templates that individuals use to process and organize self-relevant information (Markus 1977). These self-schemas not only help individuals to organize past behavior but drive and predict future behavior. For example, the likelihood of a college student consuming alcohol is affected by whether the student's own self-schema incorporates a self-concept in which the students would consider himself a consumer of alcohol (Lee et al. 2018). This suggests that future behavior is less situationally dependent and relies more on that internal template of the self.

Social Identity Theory

As humans are inherently social creatures, we develop self-schemas that reflect both our personal identities and our social identities (Horowitz 2012). Our self-concept is significantly impacted by the groups that we perceive ourselves to be a part of. According to social identity theory, our self-identity is largely defined by membership in various overlapping groups (Tajfel and Turner 1979). These social groups, or social categorizations, help to assist individuals in ordering the social world, providing a sense of self-

identification in social terms and creating boundaries, guidelines, and scripts for functioning in the social world. Thus factors such as one's political or religious affiliation, favorite sports team, or weekly book club influence the way in which one conceptualizes the self. Through these affiliations, persons not only think of themselves as a member of these groups but also think of themselves as the type of person that is consistent with these groups. In other words, individuals integrate their affiliated social groups into their self-schemas.

Kinship

Kinship can be defined as the network of relationships that an individual possesses and regards as close, important, personally influential, supportive, and permanent. Kin are "our people" (Faubion 1996). Anthropologists have formulated various theories of kinship, each theory based upon the purpose of the kin relation. Group viability and reproduction, standards for interactions between groups, and standards for the passing on of wealth have all been suggested as the purpose or role of kin relations. Although each of these theories may have merit, kinship also provides individuals with key social groups (e.g., national heritage, religious faith, or political party identification) around which one may anchor their self-concept. An individual often aligns with a variety of social groups, both biological in origin (e.g., ethnicity) and sociocultural (e.g., footballers). Kinship is unique among social groups in that an individual cannot easily change their affiliation, as one may with sociocultural social groups. Additionally, kinship is the foundation of one's other biological social groups. That is to say, one's biologically based social groups, such as ethnicity, exist as a product of one's kinship.

One long-standing question in evolutionary theory was answered through the development of inclusive fitness theory (Hamilton 1964). Why will humans often assist kin, even at great personal expense? This behavior may be explained by inclusive fitness theory, which suggests that
